Table of contents

Preface xix

Academic technology committee xxi

1 *Coal mine safety*

Study on integrated fire-fighting technology of fully-mechanized caving mining of the deeply inclined combustible thick seam 3
H. Wu, C. Xu, S. Yuan, H. Yao & Z. Zheng

The research on disturbed effects of polyurethane material's expansion pressure upon mine disaster prevention 9
G. Zou, F. Zhang & Y. Song

Research on the application of monitoring techniques of micro-seismic to water inrush forecast in Wutongzhuang Coal Mines 15
Y. Bai & J. Wang

Study on the safety advancing speed of aquifer-protective mining working face in the shallow thick coal seam 19
Y. Liu

The design of rapid prediction system on coal seam gas content 27
Y.T. Liu, J. Liu, S.Q. Ma & W. Di

Research and application of technique of injecting liquid CO_2 in goaf of Shigang coal mine to preventing fire 31
X.L. Tong, Z.A. Huang, Y.H. Zhang, Y.F. Zhang & X.T. Wang

Research on wind tunnel reducing ventilation resistance 37
J.G. Zhang

Research on the application of controllable circulatory ventilation in the mine 41
J.G. Zhang

Research on terminal mining support technology of the hard stratified roof in the fully mechanized coal face 47
L. Chen, G.Q. Hao, P. Liu & Sh.Ch. Peng

Comparative experimental study on dynamic mechanical properties of anthracite and limestone 51
Y.C. Miao & Y.K. Fu

Research on the burst triggering mechanism under the coupling action of higher stress and gas pressure 57
L. Qi, X. Chen, G. Cheng & Y. Cheng

Characteristics of electromagnetic signals obtained during blasting rupture of coal in excavating workface 63
C. Wang, C. Li, J. Wang, P. Hu, Y. Cui & X. Xu

Detection method and abnormal characteristics analysis of TEM in coal mine 71
Q.H. Liang

Calculation of the natural wind pressure of mine based on working-condition adjusted of mine main fan 77
L. Chen

Study on new hydraulic support and technology of top-coal caving at the ends of fully-mechanized working face 81
Y. Liu

Study of reliability of on-line monitoring system for mine hoist braking system 87
H.B. Qiao, K. Liu, Y.L. Wang & H. Yu

Study on the prediction model of gas emission for coal beds based on the EMD and BP-ANN 93
L.N. Zhang, D.C. Lin & J. An

Electromagnetic method in detecting water hazards in coal mining face 99
X. Shi & Y. Hou

Evaluation and applicability study on prediction methods of water inflow in mines 105
H.Q. Lian, X.X. Xia, B. Xu & H. Xu

The application research of mine gas and the fire-reversed stove gas mixing 111
G. Meng & H. Guo

Technology of controlling upper corner gas by pneumatic fan with vortex zone replacement 115
X.X. Chen, W.G. Jin, L. Gong & H.T. Li

The prospecting technology for water enrichment of water-inrush geological structure in mine 121
W. Yang

Determination of mine ventilation resistance and analysis on ventilation systems in the No. 4 mine of Pingdingshan Coal Field 127
Y. Hu, Y.F. Weng & L. Zhang

Design of mine monitoring system based on ZigBee and CAN 131
D. Liu, J. Wu & H. Liang

Development and application of gel foam materials for fire prevention and extinguishing 135
Z. Xie, T. Luan & Y. Zhang

The research on water inrush from overburden and early warning technology according to electrical characteristics in Qidong mine 143
Y. Zhang & H. Huang

Study of key technology for gob-side entry retaining in high gas coal face 149
J. Xing, P. Dang, Z. Li & W. Li

Fractured zone roof grouting reinforcement technique 153
Z.W. Zhu & C. Wang

Method of choosing optimal features used to Intrusion Detection System in coal mine disaster warning internet of things based on Immunity Algorithm 157
J.W. Zhao, Y. Hu, L.M. Sun, S.C. Yu, J.L. Huang, X.J. Wang & H. Guo

Non-Darcy seepage and stopped floor water inrush prevention 163
J. Wu & S. Yin

The study on the principle of the compound perforating technology to improve rate of gas extraction 167
J.D. Xu & X. Yang

Method of detecting in coal mine disaster warning internet of things based on SVM intruders optimized by Genetic Algorithm 171
C.L. Wang, L.M. Sun, S.C. Yu, J.L. Huang, X.J. Wang & H. Guo

Experimental study on the impact of complex surfactant in coal-water contact angle 175
L. Jin, N. Jiang & S. Chen

Research on method of automatic recognition of coal mine water inrush sources based on Immune Algorithm and Back Propagation Neural Network 179
S.C. Yu, L.M. Sun, J.L. Huang, X.J. Wang & H. Guo

Gas drainage technology of inner interlocked low tail laneway in extraordinarily high gas working face 185
Q. Ye, Z.Z. Jia, H.Z. Wang & Y. Pi

Research on airflow catastrophic of side branches induced by gas pressure in upward ventilation 191
A. Zhou, K. Wang, Z. Wu & Y. Jiang

Experimental study of horizontal strata deep rock roadway crack propagation and strength criteria 199
M.C. He, Y.Y. Peng, F. Zhao, Y.B. Wang, Y. Zhang, Y.Q. Sun & W.L. Gong

Research on the performance of foam agent used for mine fire prevention 205
Z.J. Tian, X.L. Zhang, R.Y. Zhou & Q. Ye

Research on efficient dust suppression measure in full-mechanized mining face 211
G.J. Yi, M.X. Jia, J.H. Wang & S.M. Wang

Risk analysis of 18 kinds of coal spontaneous combustion at Huanghua port 217
J.S. Zhang, S.M. Wang, X.L. Zhang & H.Q. Xiong

An LCA-based health damage evaluation method for coal mine dust 223
R. Tong, Y. Zhai & X. Li

The controlling techniques on floor heave of large cross section mining roadway with complicated surrounding rock 231
Q.F. Zhao, Y.H. Wang, Y.D. Liu, H.T. Li, J.J. Shi & L.Y. Shi

Study on the inhibitor rate evaluation by thermal analysis method 237
C. Xu, Z. Zheng, S. Yuan, H. Yao & H. Wu

Determination of goaf "three zones" scope in Pang Zhuang mine and fire prevention technology 245
Z. Xie & K. Wang

Active pressure determination under the condition of rapid determination of gas pressure 249
S. Yang, G. Cheng & L. Qi

Study on effect of gas adsorptive constant under electro magnetic fields exerted 253
L. Zhang, X. He, J. Yue & E. Wang

Hazard prediction and prevention of rock burst in island working face 257
S.S. Guo

Research on technology of paste-like filling mining under villages 263
Y. Dong, Y.C. Huang, L.C. Shao, K. Wang & Z.J. Duan

Study of rockbolts nondestructive detecting based on improved immune Danger Theory 269
X. Sun, Y. Zhao, J. Cheng & X. Sun

Experimental study on fireproofing performance of active explosion suppression system 275
Y.Y. Wang, J.F. Wang, Y.L. Zhang, J.M. Wu & S. Liu

Influence of concentration distribution on gas explosion shockwave in tunnels 279
J. Chen, L. Pang & Q. Ma

The application of the relaxative operator theory to predict the emission volume of gas in coal mine 283
L. Tan, Y. Xue & H. Ju

Outburst prevention technology and effects of hydraulic flushing with effects of pressure relief and increasing permeability 287
W. Meng & B. Li

Experimental research on major properties of the sealant to control toxic and harmful gases leakage in coal mine 293
J. Li, F. Song & H. Kang

A new borehole arrangement for draining the methane in mining induced fractured zone and the utilization of the drained methane in Yangquan Nanzhuang Coal Mine 299
D. Zhang, J. Zang, Y. Jiang & K. Wang

The empirical analysis of ARIMA multiplicative seasonal model to forecast the total number of coal mine accidents 305
L. Liu, H. Yao & L. Tan

Monitor and control node in coal production safety based on LonWorks Fieldbus 309
T. Zhang

Study on subsidence reducing technique by continuously filling grouts into stope overburden bed-separation along the dip 313
X. Fan, X. Fan, P. Wang, L. Zhou, Z. Wang & J. Zhao

Optimization of roadway layout and its effect analysis for lower protective seam in fully mechanized caving mining 319
Z. Chang, Q. Hui, Y. Li, Z. Wang & J. Zhao

Safety evaluation model and application for purification device of sour natural gas based on risk 327
J. Yi, M. Zong & W.H. Wang

Coal mine comprehensive safety information management system based on the cloud computing 331
S.Y. Liu & T.Y. Xiong

Treatment methods of coal mining subsidence area at South Lake in Tangshan city, Hebei province 335
C. Xu, Y. Chen & Z. Li

TBM tunneling in squeezing ground: Problems and solutions 339
H.S. Ma, J. Wang & L.J. Yin

On the best escape route with multiple optimization objectives during mine fire time 347
W.M. Gai, W.M. Gai, Y.F. Deng, J. Li, Y. Du & B. Cao

Mine sewage control system using PLC technology 353
J. Jiang & X. Zhang

A brief analysis of electromagnetic interference caused by the electrical and electronic equipments in the underground coal mine safety monitoring system 359
X. Hu, J. Wang, X. Li & F. Ding

The desorption laws and diffusion model of coal gas in different particle size 363
C. Wang, S. Li, J. Liu, Y. Qin & Z. Shen

Research on heat damage control and combined technology of waste heat utilization 369
J. Ma

Research on mine refrigeration of large mines with large mining depth 373
Y. Niu & J. Wang

Application feasibility study of single based station CORS in deformation monitoring of mine slope 379
Q.B. Wei, W. Li, L.B. Gao, C. Wang & Q.L. Li

Study on building permanent underground refuge chamber in Dayangquan Coal Mine 383
T. Zhang, L. Jin, N. Gao & X. Huang

Study on distribution law of lead abutment pressure in fully mechanized caving face with large mining height 389
F.L. He, Z.Y. Liu, T.D. Li, S.R. Xie, H.K. Wu & Z. Wei

The explosion-proof design of Abandoned Mine Detection Robot 395
L. Lei, B. Zhu & R. Jia

Study on the regulation of water hazards and prevention work in Yima Coalfield 401
S.Y. Li, Z.Q. Ma, M.L. Ren & X.L. Zhang

The safety technology of head rope replacement in large friction hoisting mine 407
A.T. Balkema, G. Westers, M.J. Dong & F.Y. Jia

Kinetics study on anthracite coal oxidation at low temperature by thermal analysis 411
X.X. Zhong, G.L. Dou, Y. Chen & D.M. Wang

Research on thermal stability of new-style foamed gel 417
S. Yu, H. Zhao, X. Chen & G. Meng

The application research of K shortest path algorithm in avoiding mine disaster 423
F. Wang, H.G. Guo & G.J. Lu

Study on goaf spontaneous combustion prediction simulation of gas-drainage in spontaneously flammable and thick coal seam 427
Z. Zheng, Q. Zhang, C. Xu, C. Ma, H. Yao & H. Wu

A study of GM (1, 1) residual correction model in gas concentration prediction of heading face 433
B. Wu, Z. Liu, Y. Zhou & P. Lou

Study on barrier door of gas explosion with foam ceramics as the main body 439
J.H. Sun, Z. Qu, H.Y. Fan & C.R. Wei

Prediction of coal and gas outbursts with random forests 445
Y. Lin, X. Lu & J. Fan

Goaf frictional ignition and its control measures in underground coal mines 451
G. Wang, T.X. Ren & C. Cook

The water hazards caused by burst of overburden strata separation and the control strategies 461
J.M. Wang & H. Huang

Research on multivariate hierarchical analysis and evaluation on rock burst hazard 467
Z. Yu, F. Jiang, Q. Zhu & J. Li

Study on stability of thick-hard key stratum based on numerical simulation in longwall mining 477
Z. Yu, F. Jiang, Q. Zhu & S. Zhu

Research on the free radical affecting methane outburst within coal under the electromagnetic radiation 483
M. Shang-Quan & F. Jing

Study on safety monitoring system of mine machine 487
W. Zhao, S.M. Wang & S. Qiao

2 *Metal and nonmetal mine safety*

Numerical investigation of three-point bending fracture test on granite 493
H.J. Wang, D.A. Liu, J.R. Niu, Z.D. Cui & F. Zhao

Potash exploration overview and safety considerations in Canada 499
J. Han, L. Piché & P. Geo

Experimental study on high temperature shear strength parameter of salt rock 505
K. Fang, Y.P. Li, W.W. Bi & J.P. Wu

3 *Mine product testing technology and safety symbol management*

Fast verification method of mining mechanical anemometers based on wind speed equivalent weight 511
W.Y. Ni & W.M. Gai

Development of a new kind of safety helmet of underground miner for emergent hedge 515
X.M. Liu, Y.K. Gao, Z.A. Huang, Y.H. Zhang, Y.F. Zhang & Q. Zhao

The research of dynamometer for anchor cable in mine tunnel based on the industrial Ethernet 521
X. Li, X. Li, H. Feng & J. Liu

Research on safety lead-acid battery charger in coal mine 527
Q.Z. Zhang & M.Y. Xu

Studies on the large capacity mine lithium ion battery intelligent charger 531
Z. Quan-Zhu, S. Xiao-Lei, D. Yong-Hong & M. Hong-Mei

The structural optimization and numerical simulation of wet centrifugal precipitator in fully mechanized heading face 537
H.F. Yao & P.J. Hu

Literature-based study of warning sign and of its effectiveness 543
C. Ma, S. Jia & Y. Zhang

Study on special protective clothing of coal mine 551
J. Yao & D. Tian

4 *Mine rescue tools and techniques*

How to improve the psychological quality of mine rescue commanders and fighters 559
Q.Z. Li

Assessment of Emergency Preparedness Effects of work safety in Xinjiang autonomous region of China based on weighted Rank Sum Ratio 563
W. Zhang, F. Kong & T. Jiang

Application of reverse circulation DTH hammer in mine rescue drilling 567
F. Kong & X. Lai

Study on chemical oxygen source in underground emergency refuge system 571
S. Wang, L. Jin, S. Liu & Z. Zhang

A probe into the working procedures of crisis public relations in mine disasters 577
X. Shao, H. Xu & J. Tang

Mine rescue training programs and research 583
H. Xie & T. Yan

An completeness evaluation method of community emergency response plan 587
G. Ren

Analytical and improvement research on emergent evacuation system of terminals based on behavioral mode characteristics 593
H.X. Hao

5 *Mine safety management and standardization*

Forecasting of coal mine CBM productivity based on wavelet transform 601
H.Q. Zhou & B. Cheng

Discuss on safety training of coal enterprises 605
Q. Du & B. Kou

Study on problems of safety culture construction in coal mine and the countermeasures 611
Y. Zhao & Y. Wang

Game model and analysis of market-based refined safety management in a coal mine enterprise 615
Y. Weng

Analysis on the factors' characteristics of coal miners' safety behavior based on trajectory crossing 619
R. Ni

Human behavior classification and application in the field of work safety 625
Y. Zhang & L. Pan

Study on coal mine hazard information management system based on PDCA 631
X. Zou, H. Guan, Z. Yu, Z. Guo & Z. Zhao

Application of optimized decision-making system in coal mine hidden dangers information management 637
S.Y. Liu, M. Zhu & L. Peng

Systems thinking theory in the safety production management system construction 641
H. Liu & X.L. Wang

Research on the safety prevention measures of mine water disaster in Shaqu coal mine of Liulin region 647
X.H. Wang, Y.B. Wang, J.H. Cheng, J.J. Fan, H.J. Xu, X. Zhang & Z.W. Liu

Application of the combination forecasting method in coal mine accidents forecasting 653
J. Li & Y. Ning

A statistical analysis of coal gas explosion accidents in China 659
Y. Cui, B. Xie, J. Cao & C. Wang

Construction way on the team safety culture in coal mine 665
D. Tian, J. Yao & H. Xu

Research of distributed monitoring and management system of mine ventilation 669
X.L. Liu, B. Shen, L.H. Li, S.W. Ren, L. Zhang, K.Q. Cheng & X.Z. Xu

Selection of coal mine accident cases for training 673
W. Yang, K. Zhu, S. He, Y. Zhang & S. Gao

Research on relationship between coal mine safety input and safety performance based on system dynamics 679
B. Wu & Z.F. Liu

Study on information disclosure of especially serious accident 685
B. Wu & Z. Chen

Analysis of regularity and occurrence causes of coal-gas dynamic disasters accidents 689
W. Sheng, Z. Sheng, M. Gao & L. Yang

Comparative study on the investigation mechanisms for coal mine work safety accidents in China and USA 693
G. Mei & L. Liu

Implementation of Kaizen in enterprise HSE management 699
X. Niu, P. Yang & M. Qu

Analysis on the reasons and response measures for accidents of dangerous chemicals transport 705
Q. Bu, J. He & X. Tong

Coal mine accident human error model construction and team safety management mode analysis 711
J. Chen, Q. Cao & Y. Yang

Analysis on ERP implement in coal enterprises based on management mechanism innovation 717
Y. Wang, J. Wang & S. Shao

Application of fuzzy comprehensive evaluation for mining idlers' performance 721
Y. Xing

Function principle and empirical research of "zero accident" concept 725
Z.M. Liu, G. Fu & H.B. Pei

Analysis and statistics of workers' unsafe acts in coal mine gas explosion 731
W. Yin, G. Fu, P. Gao & C. Yang

Study on STOP applied to safety management of coal mine 737
Y. Yao

The implications of behavior-based accident causation "2-4 model" in the prevention of coal mine roof accident 741
P. Gao, G. Fu & W.T. Yin

Research on safety management capability of coal enterprises of strategic orientation 745
H.L. Qi & Y.C. Ning

Influence of underground noise to people's unsafe behavior in coal mines 749
G.Y. Cheng, S.J. Chen, J.L. Qi & Y. Cheng

A brief analysis on Chinese classical philosophical thoughts and the idea of safety 753
G. Xu & G. Xu

Social structural analysis of mine accident 759
F. Lu & Y. Yan

Discussion on the management system innovation about safe development of China coal mining industry 763
J. Zhang

Grey system theory-based overseas investment risk assessment for mining enterprises 769
J. Han

Cause analysis of behavior of the secondary accidents in coal mines and the prevention 775
S. Zhang, G. Fu & S.H. Shi

Analysis on relationship of construction accident probability and safety training 783
Z.M. Liu, G. Fu & H.B. Pei

6 *Mine safety science and theory*

Analysis of mine pressure factor of dynamic disasters to coal seam with large dip angle 791
G.Q. Hao & C. Li

Mechanical mechanism analysis of forming grouting seepage channel in clay sand medium 795
H. Shi & D. Tian

Mechanism study on gas diffusion through coal particles base on mass transmission fundamental 799
Z.L. Wang

Cooling parameters fitting analysis in long distance excavation roadway 803
Z. Chu, X. Zhang, J. Ji, Y. Zhang & W. Baoqi

Study on acoustic emission and damage during the failure of coal rock 807
Y. Wu, H. Liu & S.M. Zeng

Study on numerical simulation for the fracture law of gob-side entry retaining roof 811
J.J. Shi, H.Y. Shi & J.Zh. Guo

Numerical simulating research on changing law of humidity in refuge chamber 815
Y.H. Zhang, Q. Zhao, Z.A. Huang, Y.F. Zhang, Y. Tian & Y.K. Gao

Medium characteristics and water transmissibility of carbonate strata on Ordovician top in Pingshuo, China 821
Y.M. Qi, H.B. Bai, X.E. Zhao & B. Luo

The abutment pressure distribution of extremely thick seam top coal caving longwall panel: A case study 827
H. Nan

Research on the fractal characteristics of pore structure of coal particles based on low temperature nitrogen adsorption method 831
L.C. Dai, B.S. Nie & L. Li

Research on experiment test system of mechanism of fame propagation for gas and coal dust explosion 837
L. Zhang, L. Liu & J. Xu

Numerical simulation of W-type ventilation in goaf of spontaneous combustion and gas migration 843
J.J. Liu, D. Wang & J.L. Gao

Numerical simulation study on permeability and humectant properties of coal seam water injection under high water pressure in long drilling hole 851
Y.B. Yu, W.M. Cheng, G. Zhou, L.J. Chen, L. Zhang & G.M. Liu

Dimensionless analysis in mathematical model of gas emission in coal particles 857
Y.P. Qin, Y.J. Hao, P. Liu & J. Wang

Analytical study of the time varying diffusion law of the gas in the pea coal 863
B. Cheng & H.Q. Zhou

Safe and high-efficient mining model in old mining area and resource integration mines 869
H.T. Li, L. Zhang, Y.F. Weng, H.T. Li & J.G. Yang

A numerical simulated study on the permeability and the rule of stress distribution on working face 875
X. Song & Z. Xie

Study on the optimization of ventilation system in Zhongxing coal mine 879
X. Song & Z. Xie

Multifractal characteristics of coalfield faults and gas-geological significance 883
P. Chen, E.Y. Wang, Z.T. Liu & Z.Y. Sun

The reasonable narrow coal pillar width along gob research of the deep dynamic pressure conditions 891
Z.W. Zhu & Z.J. Wen

The mechanism of coal fatigue failure and its numerical analysis under pulsating water pressure 897
H. Zhu, M. Zhang, J. Shen, B. Lei & G. Jia

The law of gas releasing in heating and oxidation process of coal 903
H. Wang, B. Yu, X. Cui, M. Chen & L. Geng

A new mathematical model of the relationship between gas desorption index of drill cuttings and gas content 907
K. Shen & H.Q. Zhou

Based on simulate test to research the law of CO newly generated when external oxygen involved during the coal breaking process 911
X. Wu, Q. Qi, X. Zhou, Z. Dong, S. Huang & Z. Liu

Feasibility of mining under water based on detecting height of water flowing fractured zone 915
B. Gao, Y. Liu & T. Yuan

Study on the deformation mechanism of deep soft rock tunnel and its control 923
H. Luan, D. Kong, Z. Wang & W. Sun

Theoretic seepage model of "water-rock-structural plane" considering the hydro-mechanical coupling mechanism 927
K. Man, J. Wang, R. Su, X. Liu, Y. Zhao & B. Zhao

Laboratory study and prediction on coal permeability of Qinshui Basin 935
G.Q. Zheng, B.C. Ling, X.Z. Zhu, J. Pan, Z.J. Pan, L.D. Connell & S.H. Tang

Impact of air-return lane and gas drainage lane spacing on surrounding rock stress 943
Y.C. Lyu, M. Wang & Y.W. Wang

Research on distribution and evolution patterns of abutment pressure in front of the fully-mechanized working face of "three-soft" coal seam isolated island 949
W.Q. Xu, E.Y. Wang, Z.T. Liu, E.K. Hou, S.J. Wang & Z.S. Deng

Study on safety theory of rheology-mutation based on system life cycle 957
X.Q. He & D.Y. Zhao

The law of gas accumulation in top-carving area of roadway and its treatment method 963
C. Chen, B. Wu, H. Wang, Y. Ding, X. Cui & Y. Zhu

Unsafe act analysis on major and particular major flood accident in coal mine 969
Y. Chun, J. Dong, B. Lu, S. Shi, S. Yuan, P. Gao, Z. Chang, Z. Chen & G. Fu

Numerical study of fluid flow and convention heat transfer in sandstone as a porous media 977
W.L. Gong, D. Liu, P.Y. Guo, H. Zhang, Y.B. Wang, Y. Zhang, B.J. Liu & Y.Q. Sun

Research on the adaptability large mining height fully-mechanized mining equipment to panel mining of unstable coal seam 983
H.X. Wen, Y.D. Liu & X.T. Meng

The study on dynamic early-warning of coal face gas emission based on extension theory 987
B. Lei, B. Wu, Y. Peng & C. Wang

Study on mining pressure appearance feature in shallow-buried fully-mechanized longwall face 993
Y.F. Ren

Numerical simulation of blasting effects on soft coal under different confining pressure 997
H.Q. Zhu, S.H. Zhu, G.W. Jia & Z.Y. Song

The research of high-altitude mine ventilation optimization decision theory based on Analytical Hierarchy Process (AHP) 1003
H. Wang & K. Zhang

Study on the stability of roof based on Mathews method in deep mining 1009
B. Zhang, C. Wang & L. Wang

Burning characteristics of No. 6 coal seam at mine field's two wings in Cuijiazhai mine 1013
Y.H. Wang, H.T. Li, Q.F. Zhao, J.J. Ren, S.S. Yang & Z.J. Shu

Study on influence of propane for the generating kinetics of multi-component gas hydrate 1017
Q. Wu, Q. Wu, B. Zhang & X. Gao

Microcirculation of air leakage of gob-side coal pillar in fully-mechanized face 1023
H.Q. Zhu, S.H. Zhu, S.L. Feng & G.W. Jia

Effect of hydrate crystal type on mechanical properties of gas hydrate-bearing coal 1029
Q. Wu, F. Zhu, X. Gao & B. Zhang

Numerical study of heat convection caused by two-phase flow confined in underground heat-exchange tunnel 1033
W.L. Gong, D. Liu, Y.Q. Wu, Y.Y. Peng, Y. Zhang & B. Liu

The research of realizing the mine safety of ascending vessel undertake force by using 2 force stem mechanical characteristics 1041
A.T. Balkema, G. Westers, F.Y. Jia & M.J. Dong

Research quantitative model of gas pressure gradient and in-situ stress in complex tectonic outburst coal seam 1045
D.X. Qin, M.B. Zhang, B.L. Lei, X.Y. Kang & A.Y. Zhu

Experimental research on movement law of coal-bed methane including temperature and confining pressure effects 1051
Y. Kang, X. Gao & C. Pan

Experimental simulation for "sorting" effect after gas and coal outburst in blind draft 1055
B.S. Nie, W.X. Hu, L.L. Yang & J.W. Chen

Study on the law of mining-induced fractures field evolution based on similar simulation experiment 1061
Y. Wu, B. Wu, M. Hua & Z. Guo

Study on abrasivity characteristics of surrounding rock in long inclined-shaft of coal mine by TBM techniques 1067
H. Jiang, Y. Jiang & J. Zhang

Protected range extension of mining underlying protective seam with long distance 1073
T. Yu, J. Sun, P. Lu & H. Guo

Study on Weijiadi coal mine geological structure characteristics and gas occurrence regularity 1079
S. Shao & J. Zhang

Numerical simulation on goaf gas extraction by the ground drilling 1083
Z. Ma, J. Zhang, Y. Xie, Q. Feng & J. Dang

Study on the similar experimental model and flow field distribution law of stope 1087
Y. Qin, S.Q. Yang, C.L. Jiang, J.Y. Lun, G.X. Zhang & J. Niu

Uncertainty analysis and evaluation of gas flow measurement 1095
P. Lu

Coupling model and its application to dynamic failure for hard coal containing gas 1099
C. Wei, H. Li & B. Li

Preface

As societies continue to grow and develop, the demand for energy has been on the rise worldwide. In China, coal is still one of the principal energy resources and more coal mining projects are needed in the future. As mining operations continue to increase their production rates and discover more ore reserves, the problems of mine safety science and engineering have become more present. There is a greater need more than ever before to better understand these problems. Based on the success of first international symposium on mine safety science and engineering, the second conference also brings together researchers from around the world to present and discuss their research findings on mine safety techniques and technologies, methods and approaches, as well as problems and issues, all with the goal that we improve the safety of our mines worldwide.

In this symposium, the peer reviewed papers were published in this proceeding, which is very important to share mine safety technology with worldwide researchers. And we hope to see you in next conference in the future.

ABSTRACT: To solve the technical problem of spontaneous combustion prevention and control in fully mechanized caving mining gob of deeply inclined thick coal seams, the characteristics of spontaneous combustion of deeply inclined was analyzed systematically. Based on the selection of index gases and determination of spontaneous combustion danger zone, the technology of low air quantity ventilation, nitrogen injection in goaf, buried grouting, injection FR-1 inhibition and inserting and masonry retaining walls can be used for ensuring the safety and efficiency of the 065-2 fully mechanized caving face. The research results have an important demonstration guidance significance and application for fire prevention in the gob and safety production of other similar mines.

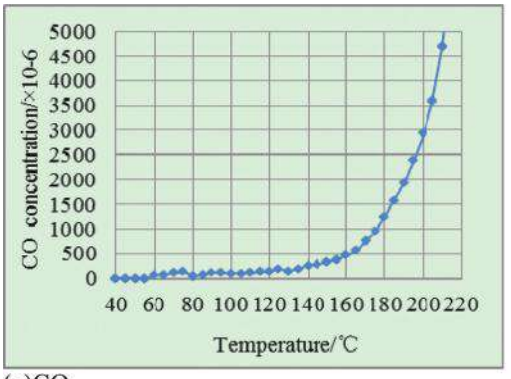
1 INTRODUCTION

The deeply inclined seams are defined by the coal seams which pitch are between 35~55° (Wu et al. 2000). Their reserves account for 14% of total coal reserves in China. More than 50% of the mining coal seams in west are the deeply inclined seams mainly distributed in the Sichuan, Xinjiang, Gansu, Fujian, Guangdong, Inner Mongolia and northeast provinces (regions). The deeply inclined seams are difficult mining for low mining production efficiency, bad safety benefits and harsh operating environment (Zhang et al. 2010). So the major coal producing countries exploit hardly these kind seams. Only a few countries are small-scale mining for experimental study. The technology of fully mechanized coal mining of the deeply inclined seams has been obtained success in different degree in China. But there are still some questions about spontaneous combustion prevention and control, which need deeply research and practical explore (Li 2006, Zhang 2009).

The 065-2 working face in gushan mine of Inner Mongolia Pingzhuang Co., Ltd. is the main production face, of which the average length is 926 m and the average inclination length is 78 m. The industrial reserves are 91.6 million tons and mining period is 1 year. Whether can safe and highly efficient extraction or not directly affects the economic and social benefits of gushan mine. It is the current pressing issues. The average mineable thickness of the coal seam is 7.5 m. The seam inclination is 34 degrees. And mining method is the technology of fully mechanized coal mining of the steeply dipping thick seam. Spontaneous combustion of the 065-2 working face is serious and its spontaneous combustion stage is one to three months. There are the fire areas of shallows mall coal mine and gushan No. 1 mine around the work-face. The upper of the 065-2 working face is goaf of the 065-1 working face, where exist coal spontaneous combustion hidden trouble and menace seriously the safety of the coal production. Although some measures of spontaneous combustion prevention and control have been taken to the fire area of shallows mall coal mine and gushan No. 1 mine, there is still of big hidden danger. Meanwhile, it is a new technical problem of spontaneous combustion prevention and control of the fully mechanized coal mining of the steeply dipping thick seam.

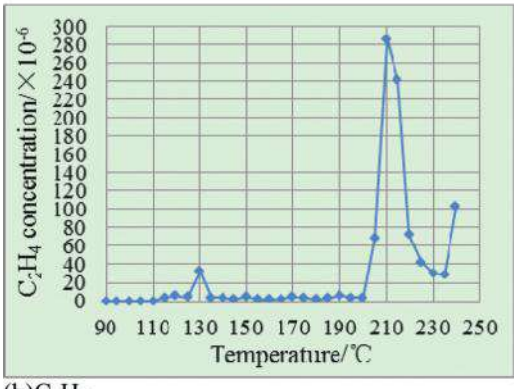
2 THE CHARACTERISTICS OF SPONTANEOUS COMBUSTION IN GUSHAN MINE

1. Strong coal spontaneous combustion tendency. The spontaneous combustion stage of seam containing fusains is general one to three months and the shortest one is only 15 d.
2. Slow drawing speed of working face. The geological conditions of coal seam are complicated because the major tectonic is faults and intrusions in the area. Meanwhile, there are unclearly small coalfield fire areas.
3. The falling height and volume increases and the uncertainty and concealment of fire location strengthen for large inclination (Chang et al. 2009).
4. Mine fire generally occurs in deep area where has a certain distance from coal exposed surface.
5. It is difficult to achieve the requirements of fire prevention and control of the traditional anti-fire fighting methods such as thick loess grouting, spraying separating agent and so on for large inclination.



3 PREDICTION TECHNOLOGY OF COAL SPONTANEOUS COMBUSTION

3.1 *Index gases*



As shown in Fig. 1, the appearance temperature of CO is about 55°C. When the temperature is lower than 130°C, CO concentration presented linear increase and when the temperature is higher than 130°C, its concentration presented exponential increase. In the case of the air volume is not mutated, when CO concentration is high and rapid increase, it shows that coal there is some trends of coal spontaneous combustion, which can judge the degree of development of the coal spontaneous combustion.

The appearance temperature of C_2H_4 is about 109°C. C_2H_4 concentration presents a tendency of slow increase at first and afterwards it decreases between 110°C~130°C. It is a lower value between 140°C~200°C. When the temperature is higher than 200°C, the gas concentration increases rapidly, then it becomes smaller.

The ignition temperature of the coal samples is about 340°C according to spontaneous combustion characteristics experiments of coal samples of the 065-2 working face in gushan mine. The spontaneous combustion index gas system with CO for main index gas and C_2H_4 for auxiliary was established when the effective forecasting temperature was below 220°C.

(a)CO

(b)C_2H_4

Figure 1. Relationship between the gas generation concentration and temperature.

3.2 *Distribution regularity of spontaneous combustion "three zone" in goaf*

The distribution of oxygen concentration in goaf is one of the important criterions of spontaneous combustion danger zone (Sudhish C.B. 1985). Grasping the distribution law is the important basis and dependence of effective technical measures to prevent coal spontaneous combustion. The variation of oxygen concentration in goaf with the advance of the working face was detected by the embedded bundle tube sampler (see Table 1).

The spontaneous combustion "three-zone" is divided in goaf using O_2 index. The oxidation zone is defined by the area of the oxygen concentration which is from 18% to 8% (Wang 2008). It would be possible to obtain the range of spontaneous combustion "three zone" that non-ignition zone is 0~15 m, the spontaneous combustion zone is 15~45 m and the suffocative zone is over 45 m.

Table 1. Monitoring results of goaf oxygen concentration in the 065-2 working face.

Embedding goaf distance/m	Oxygen concentration (O_2%) of the measuring points				
	1#	2#	3#	4#	5#
0	20.2	20.20	19.82	19.78	19.56
3	19.97	19.67	19.21	19.13	17.46

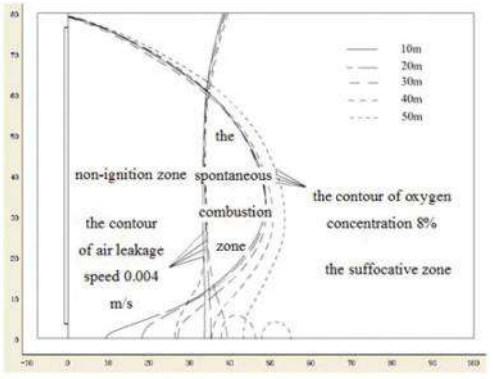
4 INTEGRATED FIRE-FIGHTING TECHNOLOGY OF 065-2 WORKING FACE

4.1 *Low-volume air ventilation*

Theory research and production practice shows that using the low-volume air ventilation in the working face to reduce breathing of gob effectively is the fundamental technology for spontaneous combustion prevention in goaf (Zhou et al. 2010). In order to get the effect rule of air volume changes on the spontaneous combustion "three zones" in gob, the change rules of oxidation heating zone in goaf under different air volumes have been simulated, and air volumes of simulation are respectively 642 m^3/min, 800 m^3/min, 900 m^3/min, 1000 m^3/min. The change rules of spontaneous combustion "three zones" of goaf in simulation results are shown in Table 2.

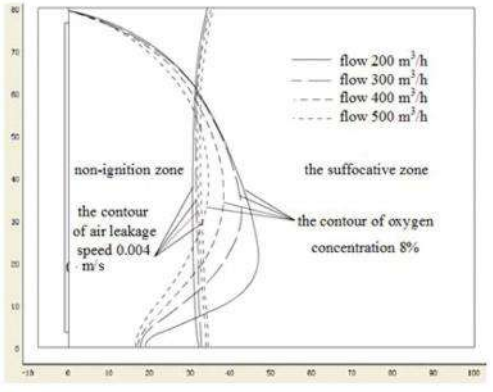
As seen in Table 2, with the increasing air volume of working surface, the position of oxidation heating zone moves to the deep gob, and rendering the trend that the width of oxidation heating zone increasing obviously. From the angle of preventing spontaneous combustion in gob, it should be minimized the width of oxidation heating zone as much as possible and the air volume of working face as low as possible. So the lowest supplying air volume of 065-2 mechanized caving face should be 525 m^3/min which is calculated according to «Coal Mine Safety Regulations» and «Operating procedures of 065-2 mechanized caving Face». Considering the instability of ventilation status in working surface, air volume can be increased moderately and the reasonable air volume range of 065-2 mechanized caving face is 578 to 656 m^3/min according to the air volume surplus coefficient of 1.1 to 1.25.

Table 2. Change rules of spontaneous combustion "three zone" with different air volume.



Air volume (m^3/min)	Starting position/m	End position/m	Spontaneous combustion width/m
642	7	49	42
800	12	55	43
900	15	58	43
1000	17	60	43

4.2 *Nitrogen injection against fire in goaf*



The reasonable nitrogen injection capacity and place are the key technical parameters of nitrogen injection against fire in gob, and they play the important role in effect test of spontaneous combustion prevention and safety production (Li 2003). The influence of nitrogen injection quantity on the law of spontaneous combustion "three zone" in goaf distribution was studied by using the numerical simulation method. Combined with the spontaneous combustion period of work seam and the advancing degree of working face, the reasonable nitrogen injection position and quantity in 065-2 fully mechanized caving face have been confirmed. As shown in Fig. 2, the reasonable nitrogen injection position is 15~35 m in mined-out area and the reasonable nitrogen injection quantity is 250~350 m^3/h.

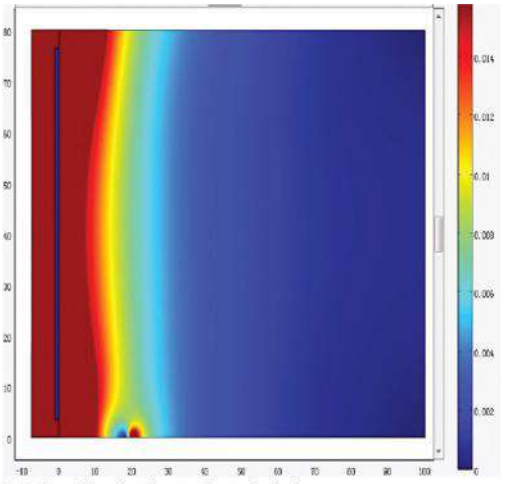
4.3 *Embedded pipe grouting in upper corner of coal face*

Embedded pipe grouting is a traditional technology for preventing spontaneous combustion in GOAF, which can fill float coal gap and inhibit the oxidation process and the heating rate of the float coal. 2.5-inch 24 meters grout iron pipes were buried along ventilation roadway in the course of actual mining of 065-2 working face. From the open-off cut, pipe should be cut off once every 48 meters along with the working face advanced. The standard of grouting quantity is seeing pulp (or water) at the position after the hydraulic supports in down-corner angle. To insure the slurry concentration, water soil ratio is not more than 4:1. Inject sludge into the gob timely along with mining work.

(a)Nitrogen injection quantity

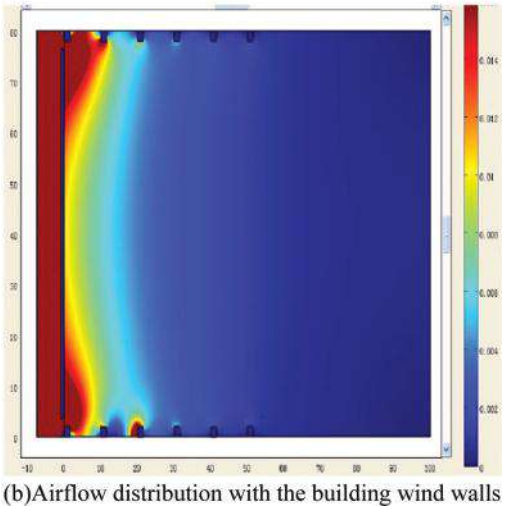
(b)Nitrogen injection position

Figure 2. Influence of nitrogen injection quantity and position on the law of spontaneous combustion "three zone" distribution.



4.4 *The diaphragm walls*

Fig. 3 shows that the comparison of the air leakage between building diaphragm walls and without diaphragm walls.



As shown in Fig. 3, the diaphragm wall in the upper and lower crossheading is effective technical measures to control gob air leaking and prevent float coal spontaneous combustion (Tang et al. 2012). Along the direction of the working face, a diaphragm wall with size of 2 × 1.5 × 2.6 m was separately built every 10 meters at the roof caving line of the upper corner and down corner using bags filled with loess and crushed coal.

4.5 *Injecting FR-1 inhibitor*

In order to produce safely and go over the fire zone successfully, mixed the FR-1 polymer liquid foam inhibitor and water according to the proportion of 1:2 (Xu 2010). Use special foam device to create the inhibitor foam. And then put out fire

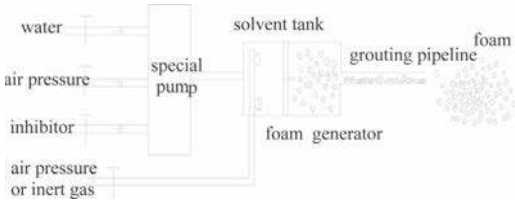
(a)The distribution of goaf airflow

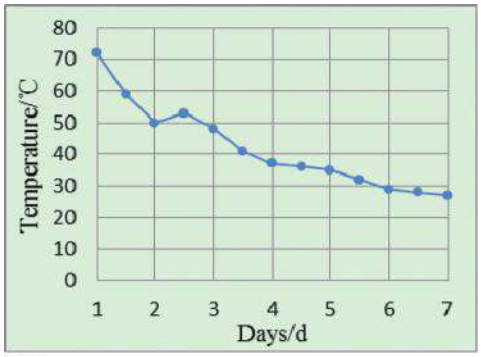
(b)Airflow distribution with the building wind walls

Figure 3. The comparison of the air leakage between building diaphragm walls and without diaphragm walls.

by means of pour this material into the hidden danger areas of spontaneous combustion through compressed air pipe or inert gas injection pipe. PU's foam equipment consists of special pump, solvent tank, foam maker and air line and so on. The equipment and technology of system bubble is shown in Fig. 4.

In across fire area stage, 135 detection holes were drilled and FR-1 inhibitor was injected into the 37 high-temperature ones. FR-1 inhibitor was introduced into the detection holes in amount of 25~100 kg daily and fill volume of 11.75~45.5 m^3. The total amount of injecting FR-1 inhibitor was 2.5 t and fill volume was 1125 m^3. Injecting FR-1 inhibitor played a significant role in





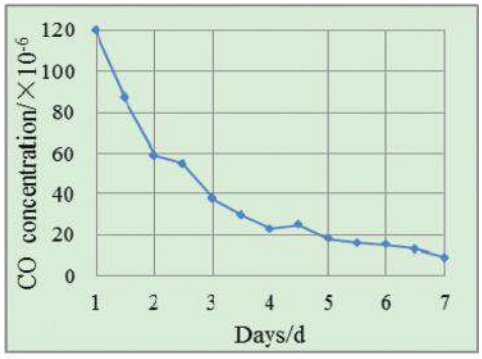


Figure 4. Equipment and technology of system bubble.

(a)Temperature

(b) CO

Figure 5. Variation of the extinguished parameters after pouring FR-1 inhibitor.

eliminating the high temperature point and preventing coal mine fire. Take B4-2 drilling of fire zone in guxin small coal mine as an illustration. CO concentration was 0.012%, O_2 concentration was 4.3%, and the gas temperature was 72°C. Inject the foam inhibitor 100 Kg to the beyond-standards danger zone by B4-2 drilling. The volume of the foam filling was 45.5 m^3 according to foam multiple of 500. Then, validate the effect through adjacent boreholes. The results of test are shown in Fig. 5. The results show that CO concentration and gas temperature decrease with injection time increased. The two indications reduced to the fire zone extinction standard of coal mine safety regulation within 4 to 5 days.

5 CONCLUSIONS

1. Based on the characteristic experiment of coal sample in spontaneous combustion, the relation of concentration and temperature of index gas generated in low temperature oxidation combustion was studied. The index gas system of spontaneous combustion was set up with CO, C_2H_4 subsidiary. The distribution of "three zones" of spontaneous combustion is determined with the oxygen concentration method. And the result shows that non-ignition zone is 0~15 m, the spontaneous combustion zone is 15~45 m and the suffocative zone is over 45 m.
2. The influence of air volume to "three zones" of mined-out area is studied with numerical simulation method, and the reasonable air volume for 065-2 fully mechanized caving face is 578~656 m^3/min. The influence of injection capacity of nitrogen to the "three zones" distribution of 065-2 fully mechanized caving face is analyzed with the method of the combination of mined-out area monitoring and numerical simulation, and the reasonable injection capacity of nitrogen is 250~350 m^3/h. The reasonable injection place of nitrogen is 15~35 m in mined-out area.
3. For the 065-2 fully mechanized caving face is crossing fire area and the point is spontaneous combustion prevention, on the basis of advanced detection and prevention of fire area, the comprehensive fire prevention technology of plugging leakage channel of the gob, nitrogen injection with buried pipe in upper and lower corner of mining face and low concentration gel injection with buried pipe in upper corner have been used. It has prevented the spontaneous combustion of 065-2 fully mechanized caving face efficiently, and has created the history of safely and efficiently crossing the continuous 260 m fire area in fully mechanized caving coal face of deep dip angle thick seam, which is 920 m long and with serious spontaneous combustion.

The research on disturbed effects of polyurethane material's expansion pressure upon mine disaster prevention

Guanghua Zou & Fengyan Zhang
North China Institute of Science and Technology, Beijing, China

Yanbo Song
Xingtai Tongcheng Coal Mining and Technology Co., Ltd., Hebei, China

ABSTRACT: With the practical effects on the rock mass space of improving the broken structure, transferring the failure mechanism, reinforcing fracture network, the polyurethane material is widely applied to the prevention of mine disasters by sealing and plugging method. Furthermore, due to the nature of expansibility, the polyurethane material produces the disturbed effects on the surrounding rocks, which causes the polyurethane material to fill in and compact the broken rock mass in further and strengthens the elastic modulus of rocks themselves, the expectation of improving the intensity of the broken rock mass achieves correspondingly.

1 PREFACE

Coalmine production, being performed underground, is imperiled by such disasters as water, fire, gas, coal dust and roof; especially the gas and coal dust explosion along with underground fire will bring an enormous damage to coal mines. To remove the poisonous gas in laneways and recover the ventilation system in dealing with explosion accidents, it is necessary to restore the destroyed ventilating devices quickly. In case of fire, it is obliged to do the hermetic seal promptly to have fire under control. The waterproof plugging material made of polyurethane elastomer, therefore, is applied to the hermetic sealing in the mine work underground.

The waterproof plugging material made of polyurethane elastomer is the resin of dual component organic polymer with such features as durability, non-shrinking, expansibility, glutinosity, impermeability, fire retardation. This kind of material should be operated with grouting pumps in coal mines underground, injecting the polyurethane agent group A and B into the sealing place in terms of the corresponding volume ratio and producing polymerization reaction to form the strengthening solid fillings. As the low viscosity of agent group A and B allows the material to permeate into the hairline cracks of the rock mass and foam to cement it firmly. Meanwhile, polyurethane material is capable of sealing gas drainage holes and the cracks around the holes to improve the effect of the mines gas drainage, of reinforcing the coal pillars of gob-side gateway and broken coal pillars and of decreasing air leakage to prevent the spontaneous combustion in the goaf. Besides, with the contribution to the reinforcement of fragile coal roof (or rock roof) and the precaution of roof fall by reinforcing the excavation and the roof of mining face, the polyurethane material is supportive of ensuring the workers' security and accelerating the production through blocking the passing water and wind to reduce and eradicate the leakage. According to the theories and practice researches, in terms of a appropriate proportion, the application of polyurethane material effectively reduces the exposed structural plane of surrounding rocks due to that the internal friction angle of the coalition is improved by an average of 10% and the cohesion by 15%.

Through constraining and consolidating the regional fractures, it increases the intensity through organic material directly filling and grouting strengthening coagulation broken free surface, to develop the anti-deforming capability of weak planes by penetrating and strengthening the rough fracture surface sliding friction, to improve the overall resistance to deformation of surrounding rock stiffness, which converts surrounding rocks stability from the weak planes control to the grouting coalition control.

Through the organic grouting and reinforcing, it changes the fractures of surrounding rocks and the rock mass from the state of biaxial stress to three dimension which strengthens the weak surface on both sides of the constraints and the continuity, transforming the failure mechanism of rock mass from the original fissure extension into the shear

failure under the action of maximum shear stress, or the tensile failure in the perpendicular direction to the minimum principal stress.

Through the organic grouting and reinforcing, it changes the proportion among the items in rock mass, developing a large system, the network skeleton structure, in broken rock mass and increasing the integrity and the resistance to external force damage.

2 EXPANSIVENESS

The expansiveness of the polyurethane slurry, as one of the important technical parameters of grouting of the organic material, can be measured with expanding multiple and expansion pressure.

2.1 *Expansion multiple*

The slurry expansion multiple along with the response time is the critical parameter for slurry grouting behavior. Greatly influenced by foaming agent added in the slurry, the expansion multiple is also related to the gas generation and its rate in the reactive process of components A and B. Expansion multiple is calculated by densimetry, which can be demonstrated by the ratio of pure slurry weight to gel weight in the same volume after the slurry reaction expansion, the expansion multiple of polyurethane material is commonly between 1~15. As far as the common polyurethane material concerned, the relation curves of the effect from the expansion multiple of slurry on the materials performance can be admeasured in a closed mould, and the relations of, elastic modulus and expansion multiple can be shown in figure 1and 2.

The figures above indicate obviously, the expansion coefficient of material which leads to degrading the resultants' mechanical performance is in the range of 1.5~2.0, and improving the expansion coefficient in further causes no reduction in the resultants' mechanical performance, after all, in most cases of deformation the expansion coefficient hardly impacts on the gel mechanical performance.

2.2 *Expansion pressure*

In the grouting process, the reaction gas generation and expansion pressure of material produce the disturbance effect of slurry and further penetration, of which the analysis on the generated gas in polyurethane material reaction and the properties of generating expansion pressure is the start point for further study on organic grouting reinforcement materials behavior. Related to the expansion multiple of material reaction, the expansion pressure of slurry reaction reaches the maximum

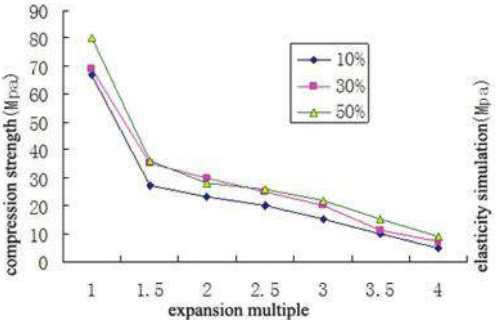

Figure 1. The relation curve of compression strength and expansion multiple.

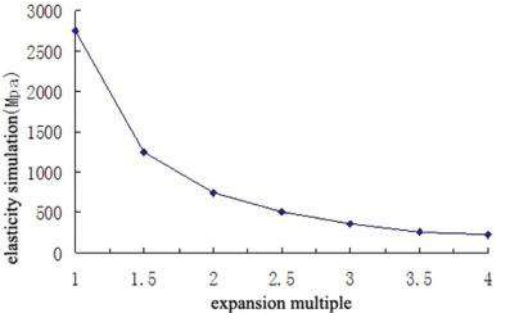

Figure 2. The relation curve of elasticity simulation and expansion multiple.

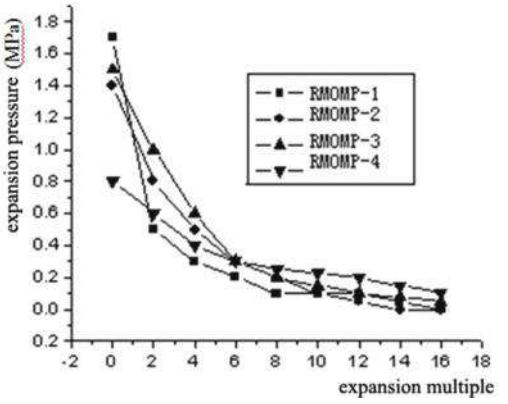

Figure 3. The relation curve of expansion pressure and expansion multiple.

under the condition of rigid constraints, however, with the increase of the material expansion multiple and the decrease of constraints, the will significantly decay, as shown in figure 3.

The slurry in grouting produces large amounts of CO_2 gas and the foaming agent into the slurry

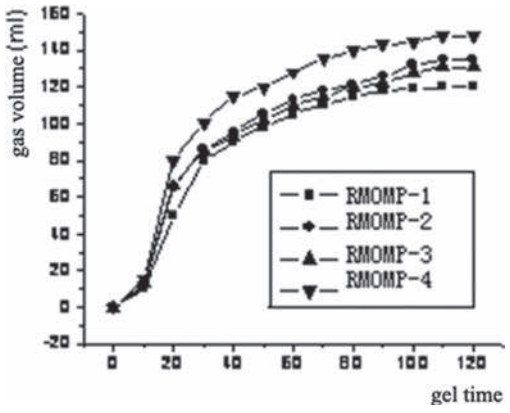

Figure 4. The curve of gas volume vs. gel time.

subsequently gasifies with the increasing of reaction temperature, being released with CO_2 from the reaction system. The gas amount and producing speed of slurry in the reaction is also one of the most important indicators for grouting. It is shown clearly in figure 4 that in the reaction the total producing amount of the gas is related to the amount of foaming agent added in the material because it produces less gas in 1 type due to the amount of foaming agent added in the slurry is only 10%, while in 4 type 25% foaming agent in the slurry leads to more gas production.

3 EXPANSION PRESSURE DISTURBANCE EFFECTS

To assume the strengthened rock stratum as the ideal elastic plastic material, in which the slurry spreads the way on its own power, producing the stress on the surrounding rock stratum and filling the cracks within the rocks, therefore, under the grouting pressure, the slurry is squeezed into the fractures and making its way to diffusion and penetration. If injected into the surrounding rocks with high pressure, the two components of polyurethane material will bring the chemical reaction in the rock mass, producing the expansion pressure and making the slurry diffusing and penetrating towards the deeper fissures till the end of the reaction.

Furthermore, under the pressure of pump and expansion all together, the spreading slurry can not only fill the fractures within the rock mass connected to others but also compact the small enclosed fissures and consolidate the broken rock mass further to increase the elastic modulus and accordingly improve the strength of broken rock mass accordingly.

The research demonstrates that the form of the slurry infused into the rock mass is irregular, which can be reduced to the approximate cylindrical in order to calculate the disturbance effect of expansion pressure. The form will be changed from the state of elastic deformation to plastic one with grouting pressure increasing around the injection holes, then it can be analyzed by the elastic-plastic theory.

Provided that under the co-action of the grouting pressure and the expansion pressure (pr), three regions will be formed surrounding the grouting pipe zone. They are the grout filling region (I), the plastic deformation region (II) and the elastic deformation region (III) of the grouting coalition. To presume that the hydrostatic stress of the injection holes is $p_{0,}$ the penetration radius of slurry is r and the radius of grouting pipe is r_0, then the stress boundary condition is

$$\begin{cases} \sigma_r = -p_c & (r = r_0) \\ \sigma_r = -p_0 & (r \to \infty) \end{cases} \tag{1}$$

$$\begin{cases} \sigma_r = -p_r & (r = r_0) \\ \sigma_r = -p_c & (r \to \infty) \end{cases} \tag{2}$$

By the differential equation of ax symmetric plane problem, physical equation and geometric equation, we get the radial stress σ_r as $r = R_0$, tangential stress σ_θ and displacement Ur:

$$\sigma_r = -p_c, \sigma_\theta = -2p_0 + p_c,$$
$$U_r = \frac{1+\gamma}{E}\left[p_c - 2(1-\gamma)p_0\right]r_0 \tag{3}$$

In the formula above, E and γ present the elastic modulus of the coalition and Poisson ratio respectively

To presume that the principle press of the coalition is $\sigma_1 = \sigma_r$, $\sigma_3 = \sigma_\theta$, when the strength condition, Mohr-Coulomb, is met, it will be changed into the plastic state. The strength condition is expressed by:

$$\sigma_\theta - \sigma_r = -2(C\cot\varphi + \sigma_r)\frac{\sin\varphi}{1+\sin\varphi} \tag{4}$$

In this formula, C and φ present the adhesion stress of the coalition and internal friction angle, with the above expression (4) substituted into this formula, we can conclude:

$$\sigma_r = \left(p_r + C\cot\varphi\right)\left(\frac{r_0}{r}\right)^{\frac{\sin\varphi}{1+\sin\varphi}} - C\cot\varphi$$
$$\sigma_r = -p_c, p_c = p_0\left(1+\sin\varphi\right) - C\cos\varphi \tag{5}$$

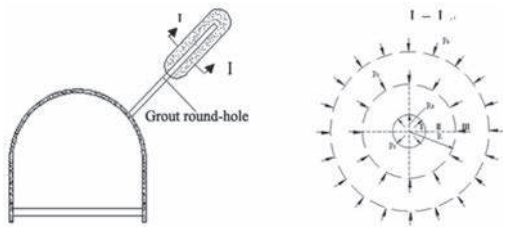

Figure 5. Grout round-hole & different stress regions resulting from grouting.

Then, there comes the formula:

$$C\cos\varphi + C\cot\varphi - p_0(1+\sin\varphi) = (p_r + C\cot\varphi)\left(\frac{r_0}{r}\right)^{\frac{\sin\varphi}{1+\sin\varphi}} \quad (6)$$

To expand this formula, we get the relation of penetration radius r and the expansion pressure p_r:

$$r = \left[\frac{C\cos\varphi + C\cot\varphi - p_0(1+\sin\varphi)}{p_r + C\cot\varphi}\right]^{-\frac{1+\sin\varphi}{\sin\varphi}} r_0 \quad (7)$$

To assume that hydrostatic stress p_0 = 3.5 MPa with the internal friction angel ranging from 37.8° to 38.5° and the internal friction force ranging from 6.8 to 7.1 MPa, the relation between the expansion pressure changes and penetration radius can be calculated in terms of the formula (7). The curve is shown by figure 6. According to the empirical data on spot, the graph of the relation between the expansion pressure changes and the grout quantity can be shown as figure 7.

From figure 6 and 7, it can be concluded that the disturbance effect of the slurry expansion pressure grout increases the diffusion radius of the slurry in the rock mass; meanwhile, the grouting quantity is also improved with the expansion pressure increasing, with conducive to the grouting.

The disturbance effect produced by expansion pressure above can be analyzed further by the circular tube model of porous media.

Taking the expansion pressure of polyurethane material into consideration, that is,

$$\Delta p' = p_0 - p_1 + p_2,$$

to expand

$$Q = \frac{4\pi k_g}{\mu_g}\sqrt{3\Delta p\gamma_g r_0^3}$$

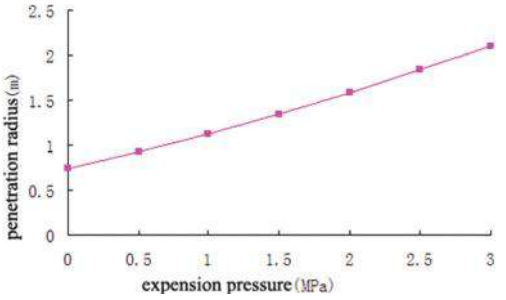

Figure 6. The curve of expansion pressure vs. penetration radius.

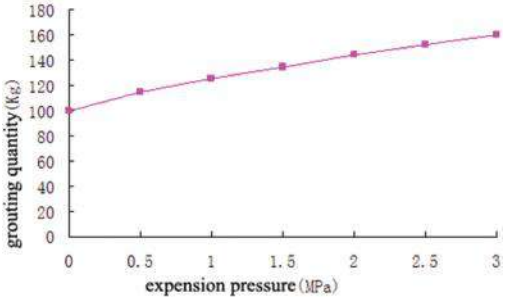

Figure 7. The curve of expansion pressure vs. grouting quantity.

and

$$r = \frac{\mu_g Q^{\frac{2}{3}}}{3}\sqrt[3]{\frac{\mu_g}{2\pi^2 k^2\gamma_g^2 p}}$$

along with the formula

$$Q = V\omega t = \omega t\kappa_g J^{1/2},$$

we get

$$dp = -\frac{1}{\gamma_g}\left(\frac{Q\beta}{4\pi r^2 tk}\right)^2 dr \quad (8)$$

To do integral on both sides of the above formula, there comes;

$$\int dp = -\frac{1}{\gamma_g}\left(\frac{Q\beta}{4\pi tk}\right)^2 \int r^{-2} dr,$$

the solution for it is

$$p = \frac{1}{3\gamma_g}\left(\frac{Q\beta}{4\pi tk}\right)^2 r^{-3} \quad (9)$$

With the boundary conditions, when $r = r_0$, $p = p_1 + p_2$, when $r = R$, $p = p_0$, thus, we get the following expressions:

$$p_1 + p_2 = \frac{1}{3\gamma_g}\left(\frac{Q\beta}{4\pi tk}\right)^2 r_0^{-3} \tag{10}$$

$$p_0 = \frac{1}{3\gamma_g}\left(\frac{Q\beta}{4\pi tk}\right)^2 r^{-3} \tag{11}$$

Then, we draw a conclusion of

$$\begin{aligned} Q &= \frac{4\pi kt}{\beta}\sqrt[3]{3\Delta p'\gamma_g r^3} \\ &= \frac{4\pi kt}{\beta}\sqrt[3]{3(p_0 - p_1 + p_2)\gamma_g r^3} \end{aligned} \tag{12}$$

Because the slurry diffuses spherically, so

$$Q = \frac{4}{3}\pi r^3 n; \Delta p' = p_1 - p_0 + p_2,$$

set into the formula above, there comes:

$$\begin{aligned} \Delta p' &= \frac{1}{3\gamma_g}\left(\frac{Q\beta}{4\pi k}\right)^2 (r_0^{-3} - r^{-3}) \\ &= \frac{1}{3\gamma_g}\left(\frac{\beta}{3tk}\right)^2 r^6 (r_0^{-3} - r^{-3}) \end{aligned}$$

For r_0 is rather smaller than r_1 then comes the formula

$$\Delta p' = \frac{1}{3\gamma_g}\left(\frac{\beta}{3tk}\right)^2 r^6 r_0^{-3}$$

The deformation is

$$r = \sqrt[3]{\frac{3kt}{\beta}} \bullet \sqrt[6]{3\Delta p'\gamma_g} \tag{13}$$

Ultimately, we obtain the strengthened grouting material with expansion pressure, of which the calculation formula of grouting quantity and penetration radius is:

$$Q = \frac{4\pi kt}{\beta}\sqrt[3]{3(p_1 - p_0 + p_2)\gamma_g r^3} \tag{14}$$

$$r = \sqrt[3]{\frac{3kt}{\beta}} \bullet \sqrt[6]{3\Delta p'\gamma_g} \tag{15}$$

In the formula,

κ–The penetrating coefficient of rock stratum, m/s;

κ_g–The penetrating coefficient of the slurry in rock stratum, $\kappa_g = \kappa/\beta$, m/s.

β–The viscosity ratio of slurry vs. water

n–The porosity factor of rock stratum with slurry

P_2–The expansion pressure value of grouting slurry

The formula (14) shows that grouting quantity is in direct proportion to the penetrating coefficient of the slurry in rock stratum, the sum of grouting and expansion pressure, the grouting time, and the drilling diameter but in inverse proportion to the slurry viscosity.

In $Q = (4\pi kt/\beta)\sqrt[3]{3(p_1 - p_0 + p_2)\gamma_g r^3}$, the main factors influencing on grouting quantity are such penetrating coefficient of rock stratum with slurry, grouting time, drilling diameter, grouting and expansion pressure and slurry viscosity. On condition that other factors are in certain cases, the analysis on the impact of grouting and expansion pressure upon grouting quantity is that the grouting pressure is the leading factor in the process, during which with the occurrence of polyurethane material's expansion pressure and without altering the grouting pressure, the total pressure difference grows to increase the grouting quantity.

It is clear that in the transfusion process of polyurethane material, the more the gas moles are produced, under the certain effect of grouting pressure; the easier it is to overcome the resistance of static grout and the viscous resistance created by slurry solidification, which is advantageous to grouting.

The gas produced outside of the gel will generate new additional grouting pressure while the one inside will form the forming structure together with gel to strengthen the force of slurry-proof or the anti-permeability. Along with the continuous grouting, more and more slurry becomes concreting to fill in the cracks.

4 CONCLUSION

1. The slurry expansiveness of polyurethane material is one of the important technical parameters of organic material grouting, which can be measured by expansion multiple and pressure.
2. As the grouting material made of polyurethane with expansion and penetrating pressure, the formula for calculating the grouting quantity and penetration radius is

$$Q = \frac{4\pi kt}{\beta}\sqrt[3]{3(p_1 - p_0 + p_2)\gamma_g r^3}$$

$$r = \sqrt[3]{\frac{3kt}{\beta}} \bullet \sqrt[6]{3\Delta p' \gamma_g}$$

Under the condition of the same grouting parameters, the disturbance effect of expansion pressure produced by the strengthening slurry of polyurethane grouting will promote the penetration radius and grouting quantity of grouting coalition, providing the grouting with the positive effects.

Research on the application of monitoring techniques of micro-seismic to water inrush forecast in Wutongzhuang Coal Mines

Yue Bai & Jingming Wang
North China Institute of Science and Technology, Sanhe City, Hebei Province, China

ABSTRACT: Water inrush from coal floor is that limestone water with high pressure under the coal seam erupts out from the aquifuge strata and the strata are broken during mining activities. Therefore, the micro-seismic will take place when coal floor strata crack. Consequently, to monitor the micro-seisms and position focal areas become the effective methods to figure out the possible inrush places. The technique on week seismic monitoring to forecasting water inrush from coal floor in Wutongzhuang Coal Mine, Fengfeng Coal Field was applied to and it is found that micro-seisms happened in the deep coal floor confining strata, in the ahead area of mining face while the seisms takes place in shallow area in the goof; the seisms appears far more frequently and its active time is much longer in the pin off area of faults than in any other intact coal floor areas and places of the faults; the place where the seismic frequently happens is easy to cause a water eruption. These phenomena are complied with the inrush mechanism of "pressured water progressively intruding up into the floor aquifuge". The monitoring result indicates that the fracturing or micro-seismic focuses and water inrush can be forecasted by means of calculating mechanics semesters inversely and mining simulation. The technique is significant to safety and efficiency production in mining and no doubt has bright future in its practical application because the water inrush is one of the main water hazards in north China coal field where is the main coal productivity area.

1 INTRODUCTION

The water inrush out from coal floor and sinking columns are one of the worst hazards in the north China coal field. According to the statistics, there have been 1282 cases for hazards resulting from water inrush from coal floor and sinking columns in the north China coal field, around 220 cases of mine flooded among them, since 1955. Consequently with the economical loss of 30 million R.M.B. Yuan. Fengfeng Coal Mining Area is one of typical areas with heavy mine flow, with hundreds of water hazards because of water inrush from the coal floor, six mines or work face flooded, among which, Wutongzhang Coal Mine share 6 water hazards caused by water inrush out from coal floor, with 17 mortality, once mine blood and work face blood respectively. Hence, investigation on the mine water hazards control is very important to safe and efficient production. Wutongzhuang Coal Mine has such a typical characteristics in the north China coal field by its hydrogeological features that the technology of water hazards control in this mine is applicable to other north China-typed coal mines.

Many hydrogeologists have been involved in the predicting or forecasting study of water hazards caused by water inrush from coal floor and sinking columns. The researches have figured out that the water hazards caused by water inrush from coal floor and sinking columns is the result from the impermeable stratum failure. Consequently, some scientists had utilized the techniques on monitoring the stress, strain, water temperature and pressure (Wang Jingming 1998), and the others using the supersonic methods (Wang Zuoyu & Liu Hongquan 1992, Chen Feng et al. 2000), and gradually in China begins the technology of micro-seism to tentatively forecast the water hazards in the coal mines (Yang Tianhong et al. 2007) in Sanhejian Coal Mine, Xuzhong (Yang Fuxing 2007) and Huafeng Coal Mine, Xinwen (Wang Jingming et al. 1996), without engineering tests. The authors utilized the technique to monitoring the water disaster from coal floor and sinking column in Wutongzhuang coal mine, and obtained validated achievements that combination of monitoring the position and regulation of a micro seismic with the hydrogeology analysis is feasible to forecast the hydrogeological conditions in the coal floor strata and sinking columns.

2 THE HYDROGEOLOGICAL CONDITIONS OF WUTONGZHUANG COAL MINE

Located at the bottom of Shanxi Group, Permian system, the major coal seam No. 2 in

Wutongzhuang Coal Mine is about 35 m to 50 m over Ye Qing limestone aquifer, and 140 m over Ordovician limestone reservoir. Without any water disaster happened in excavating coal No. 2 at other coal mines in Fengfeng Coal Mining Area, hence the hydrological condition at Wutong Coal Mine was also thought to be simple. However, there were several water disasters happened in mine construction period and operation period. The first disaster happened during excavation of the transfixion between working shaft and auxiliary shaft at station level, and caused 17 deaths. The second hazard happened in 3 first work faces due to water inrush from coal floor, and brought production stop. The third happened when the north main ventilation tunnel was excavated close to the strongly permeable sinking column and caused an water inrush with flowage of 130 m^3/h. The 24 sinking columns had been detected in the recruit geological exploration, among which three were validated, and 2 of them were strongly permeable. Therefore water inrush from coal floor and sinking column seriously threaten the coal mine both in safety and efficiency. And these have become the one of main factors to constrain the production progress. In order to predict, forecast the water disasters and to ensure the safety production, the Micro-seismic Monitoring technique was applied to industrial tests for the water inrush both from coal floor and sinking column at the work face 182106, in Wutongzhuang Coal Mine.

The work face 182106 is 505 m–707 m deep. The upper gateway and lower gateway are –506 m and –327 m in elevations respectively, and slope distance between the two gateways is from 65 to 165 m. The mining height is 3.4 m. Work faces 182105 and 182301 remain un-mined in the east and west. When the lower gateway was heading, the sinking column X3 with its diameter of about 30 m had exposed; Two faults of less than 2 m in throws had been found in the work face and faults F2 of 20.0 m maximum fall expanding from upper side work face to and tip off at the working face, as shown in Figure 1. The main work of the research was to monitor the sinking column activities and fault F2 extension.

3 SYSTEM CALIBRATION AND MONITORING METHOD

After installed and modulated, the MSM was calibrated. The parameters, such as elastic wave traveling velocity in coal floor strata, the average traveling speed in the surrounding rocks, energy attenuation rule etc. were obtained by site tests to ensure the of monitoring net to be reasonable. Both the compensation errors of every sensor and the consistency for reaching time of the waves were gained and calibrated by blasting after the MSM system had been set up.

The blasting wholes were drilled in the coal roof of monitoring areas in work face 182106. The explosive parameters can be seen at Table 1. Because the arriving time of wave P (longitudinal wave) was used in plotting wave emission source, the speed and structure of wave P are interested.

5 sensor holes and 2 calibrating blast holes were laid out in the coal floor of work face. The sensor hole are named as B1 to B5, and the calibrating blasting holes are named as C1–C2.5 three dimension sensors named as S1 to S5 were distributed in the 5 boreholes, which S4 and S5 was close to the fault in order to monitor the fault activity. Because the area between lower gateway within borehole B4 to B5 and upper gateway within borehole B1 to B3 abnormal in hydrogeology according electricity sound respecting, the 8 one dimension sensors named as D1~D8 were added there. Two one dimension sensors named as D9 and D10 were set up at the edge of sinking column due to the sinking column was dangerous in hydrogeology. The sensors layout can be seen in Figure 1 and parameters of borehole is shown in Table 2.

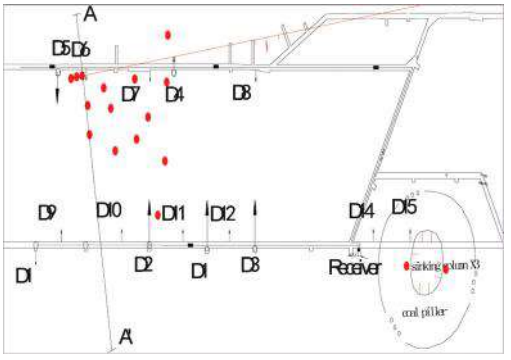

Figure 1. Chart of the sensors layout and micro-seismic plane distribution in coal floor strata.

32		27.7	60

4 THE RESULTS AND VALIDATION

4.1 *The results*

The micro-seismic can be classified into 3 phases according to their frequency and intensity, e.g. the energy accumulation phase, frequent micro-seismic phase and aftershock phase.

The energy accumulation phase: this phase covered the 115 m from the cut off to the working face. Small energy events had happened in this period at areas close to the lower gateway and the edge of sinking column, without failure in the coal floor with bigger energy.

Frequent micro-seismic phase: When the work face advanced to 115~180 m from January 25 to 28, there were 6 among 8 micro-seismic of bigger energy events took place in the phase, as shown in Table 2. Especially, 3 stronger micro-seismic occurred concentrically at the point of 45 m ahead of working face. Seismic source's depth was 25–28 m under the floor. Geology map indicated that the micro-seismic source was located at fault pin off area. According to the displacement of micro-seismic source, the fault was considered to have extended by 8 m and 12 m both in height and length during mining.

After shock phase: After January 8, only 3 microseisms with stronger energy happened in lower area of work face in the range of 181 m~291 m from the cut off during the phase, while 2 micro-seismic events with small power were detected at nearby sinking column X3 apart from work face by 425 m and 315 m respectively. Apparently, the two small power events had nothing to do with mining.

The micro-seismic events on coal floor distributed at plane and section is shown in Figure 1 and Figure 3.

4.2 *The analysis of the results*

According to Figure 1 and Figure 2, the micro-seismic appearing on the floor of work face 182106 mostly happened in lower part between the detecting holes D4 and D5. The reasons were considered as follows: (1) Based on the theory of mining pressure, The closer to lower part of inclined work face, the greater mining pressure is, and the more intensive damage of the coal floor strata. (2) the integrality of coal floor strata is ruin at lower part. Although there was no macro-factures at the fault pin off, some micro crack had been found to a limited extension because the fault F106-1 went into the interior of work face through the lower gateway of work face. According to the fracture mechanics and damnification mechanics, the stress is easy to accumulate at the end of the fault to make the fault expand.

Table 2. The parameters of borehole and sensors (only some listed).

Hole name	Sensors mane	Sensor type	Distance to cut off (m)
B1	S1	3 dimension	162.56
B2	S2	3 dimension	285.67
B3	S3	3 dimension	400.08

Dip angle (°)	Depth of holes (m)	Remark

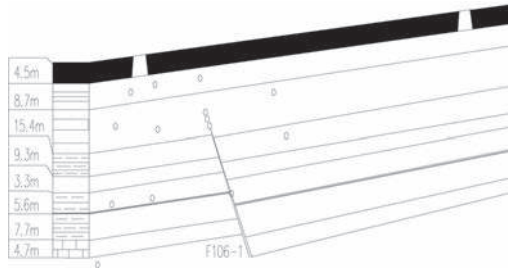

Figure 2. Projection of section A-A' for micro-seismic on floor of work face 182106.

During monitoring, 3 micseismic events with bigger energy were recorded. This means 3 propagations of the fault. There were only an interval of 5 minutes between the first and second events (as shown in first two records in Table 2). These could

be considered as the results of same mining pressure activity. The third micro-seismic event had an interval of 70 hours from the first, when the work face was advanced by about 10.5 m. Based on the former measurement to the mining pressure in Wutongzhuang Coal Mine, the roof pressure period was between 8–12 m, so the last micro-seismic event should belong to resulting from another mine pressure.

The micro-seismic event happened during mining made unfavorable effects in hydrogeology. When the sensor was receiving the micro-seismic signals, the floor of coal floor crack with big noise, and then water gushed out at the flowage of 60 m^3/h from Carbinous limestone aquifer, which was almost the same as the water inrush from coal floor as the result of floor breaking with a coinstantaneous blare happened in a work face in Coal Mine No. 2, Fengfeng Coal Area in 80's last century. It is proof that micro-seismic detecting method is an effective technique to predict water inrush from coal floor.

We can consider the pin off of the fault F106 as a hidden part of the fault under the coal floor, i.e. the fault extending down into Ordovician limestone with bigger fault throw in lower and smaller in above, as shown in Figure 2. The upward propagation of the fault testified by 2 micro seismic is confirmed with the water inrush mechanism of water progressive upward intrusion.

During detecting, there was no micro-seismic events caused by mining happened in sinking column. The reason could be as follows: (1) Because the fillings in the sinking column was mixed and lack of integrality, the fillings' brittle fracture was replaced by its plastic deformation during a mining. (2) The sinking column was grouted and the protective coal pillar was arranged. This also means that the size of the coal pillar is enough to stand the mine pressure.

4.3 *Engineering validating*

In order to detect the fault F106-1's water conductivity before mining, two boreholes through the fault were dilled and there was no water flow from the holes, indicating that the fault was impermeable under undisturbed conditions. After the water inrush happened in fault during mining, one of the holes was redrilled, and water flowed out at the rate of 30 m^3/h. This indicated that the fault became "active", and the fault zone became permeable.

5 CONCLUSION

With the whole monitoring procedure on the micro-seismic happened on floor of work face 182106 in Wutongzhuang Coal Mine which has a complicated hydrogeological condition, We have achieved the following ultimatums:

There were 25 micro-seismic events happened on coal floor of work face during the mining activity, among which 8 times of the events had the bigger energy, mostly appearing on the weakness of the floor in lower part of the work face.

Three biggish micro-seismic events occurred in the fault pin off area during mining, with the interval of micro-seismic consistency with the period mine pressure on the roof. The fault had extended for 12 m, according to recording of micro-seismic monitor. The activities of fault resulted in the water inrush from floor confirm with the mechanism of water inrush during groundwater progressive intrusion process.

The micro-seismic event has a distinct advanced sign that can be important basis for water inrush forecasting in coal mine.

There was no micro-seismic event happened in sinking column and the permeability had no obvious change with mining activities.

Study on the safety advancing speed of aquifer-protective mining working face in the shallow thick coal seam

Yude Liu
Key Laborary of Mine Disaster Prevention and Control, Yanjiao, Beijing, China
College of Safety Engineering, North China Institute of Science and Technology, Yanjiao, Beijing, China

ABSTRACT: Based on the domestic and foreign research conclusions and based on the 2_{-2} coal seam as the research object, thought of "working face advances speed depending on the overlying strata water seepage velocity" is proposed by analyzing the mechanism and key of aquifer-protective mining in shallow coal seam (working face advances speed can make broken key strata body closing before upper water seepage to mined-out area). According to the seepage theory and empirical formulas and the measured data etc., seepage time formulas and calculation of ground water in upper strata of working face is made for every classification of aquifer-protective mining. According to the key strata theory and geological data of Shendong Mine Area, initial or periodic breaking space of overlying strata is calculated for each class. Thus, the working face advance speed of each class is calculated and identified. Meanwhile, the length range of safety aquifer-protective mining face is determined by the lower limit of working face's promoting speed and cutting speed of combine. The aquifer-protective mining technology system is perfected furthermore, and theoretical guidance is provided for security applications of shallow seam aquifer-protective mining technology.

1 INTRODUCTION

Aquifer-protective mining is aimed at avoiding damage to the water-bearing structure of aquiferous layers in the process of mining by applying appropriate methods. Even there is some damage which may cause loss of some water, but the damage can be recovered within a certain period of time and it does not affect the minimal water-bearing level for the growth of ground flora.

Domestic scholars carried out in large scale field measurements. Their thorough research involved the basic mechanical properties of the major groups between coal seams and aquifer rocks. This consisted of the evolution of fractures, load transfer mechanisms, features of water-resisting and water-conduction and the relationship between major related factors of mining. Various methods and means were used, revealing the deformation and failure format of different rocks, the roof breakage mechanism and the apparent ground pressure and determined the aquifer-protective action of water-resisting layers and the controllability of water-conducting fissures.

Using Coal Seam 2_{-2} in the Shendong Mine as our research object, we analyzed the mechanism and key of aquifer-protective mining of shallow coal seams and classified its applicable conditions by using the Integrative Index Method of multi-factors. The key point in aquifer-protective mining is to ensure that the fracture zone does not break over the aquifer or the fracture which can conduct water will be closed and keep equilibrious by controlling the controllable factors under different natural conditions. The classification system has been established, as shown in Table 1.

In order to further improve aquifer-protective mining technical system, we have analyzed particularly the mining speed of each class based on the relevant theory and geology, technical conditions which may provide some theoretical directions for the application of aquifer-protective mining technology of thick coal seam.

2 GEOLOGIC ASPECTS OF SHENDONG MINE AREA

The structure of Shendong Mine Area is simple, and contains mainly Jurassic strata which with 185 m of average thickness. It has the characteristics of shallow buried depth, and thin bedrock, and thick loose sand and rich phreatic water.

2_{-2} coal seam in Shendong Coal Field belongs to Yanan group of Jurassic mid-formation, while, ranges in thickness from 3.93 to 6.71 m, and is as much as 6.18 m in average thickness. The configuration of 2_{-2} coal seam is so simple that contains about 1 to 3 strata of black shale which ranges in thickness from 0.12 to 0.37 m. The essence of black

Table 1. Classification system of aquifer-protective mining in shallow coal seams.

Class	Classes name	Main features
I	Safety aquifer-protective mining class	The bedrock thickness is usually bigger than 80 to 85 m, which meets the demand for the thickness of waterproof protection rock pillars prescribed in The Regulations of Coal Pillars Leaving and Mining in Main Lanes under Buildings, Water Body, and Railways.
II	Long-wall easy aquifer-protective mining class	The bedrock thickness is usually bigger than 70 to 75 m, the buried depth is over the shallow limit, and it has the features of compound key strata. In this case, aquifer-protective mining is relatively easy.
III	Long-wall moderate aquifer-protective mining class	The bedrock thickness is generally bigger than 60 to 65 m, having the features of single key strata or compound key strata, lying between easy aquifer-protective mining area and difficult one.
IV	Long-wall difficult aquifer-protective mining class	The bedrock thickness is usually bigger than 50 to 55 m, the buried depth is less than the shallow limit, and it has the features of single key strata. With mining at the working face, steps in the overlying rock can easily go down as a whole, and the coming pressure becomes intense.
V	Short-wall continuous water preservation continuous mining class	The bedrock thickness is usually bigger than 35 to 40 m, having the features of single key strata, and long-wall mining is not suitable.
VI	Short-wall interval water preservation continuous mining class	The bedrock thickness is usually less than 35 to 40 m, but bigger than 15 to 20 m, having the features of single key strata, and continuous mining is not suitable.
VII	Short-wall single chamber water preservation continuous mining class	The bedrock thickness is usually less than 15 to 20 m, and single chamber or room arrangement is suitable.

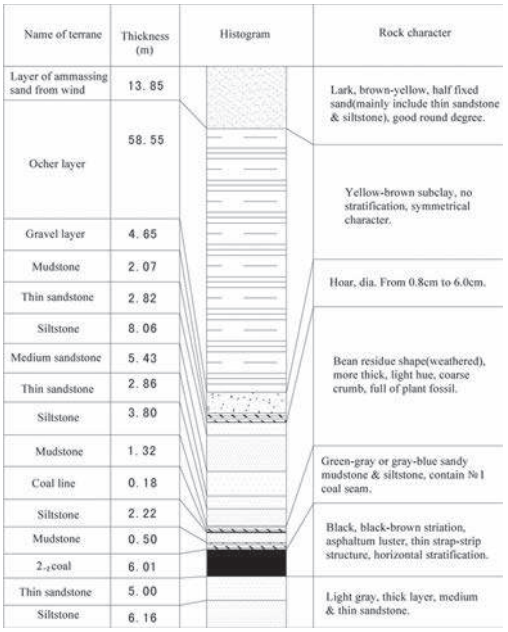

Figure 1. Pole diagram of 2–2 coal seam.

shale, commonly, is mudstone except be charcoal mudstone in some areas. Consequently, 2_{-2} coal seam could belong to stabile thick coal seam. See Fig. 1.

Underground water is mainly supplied by atmospheric precipitation, and classified three classes which are respectively the pore phreatic water of Cainozoic unconsolidated strata, the cranny phreatic water and pressure water of Mesozoic, the hole fissure phreatic water of burnt rock.

Based on the geological conditions, the long-wall fully mechanized mining technology of higher min-ing height and short-wall continuous mining technology have been used in Shendong Mine Area. The ratio of mining and caving is 1:1.3, and the caving step distance is 0.8 m. The working face's roads are supported by the combined support mode of bolt and anchorcable. The hydraulic supports among working face are ZFS-6000/17/33 type, are amount of 131 supports in the longest section of working face. Three supports are laid at each end of working face which is 6500/20/32 type.

3 TO DETERMINE THE MINING SPEED OF AQUIFER-PROTECTIVE MINING

Based on the mechanism of aquifer-protective mining, the working face's advancing speed of safety aquifer-protective mining of each class must satisfy the following conditions: the advancing speed can make the broken rock body of overlying strata to be closed before the aquifer water seep to the goaf after mining.

The speed can be shown and calculated by follow formula:

$$v_m > L_z / t_s \quad (1)$$

where, v_m is the working face's advancing speed, m/d; L_z is the initial or periodic broken distance of key layer, m; t_s is the seepage time of upper aquifer water.

3.1 *Seepage velocity*

a) The Laws of turbulent motion and laminar flow motion
Usually, the water's laminar flow motion of smaller seepage in the joints rocks obeys the Darcy Law, namely:

$$V = k \cdot I \quad (2)$$

where, V is the seepage speed of water; k is the seepage coefficient which depends on the physical characteristics of rocks; I is the water head gradient which means the water head loss of each unit length of the distance.

If in the larger gap strata or the water head gradient higher, the water move subjects to the turbulent motion laws which is as the follow:

$$V = k \cdot I^{1/2} \quad (3)$$

b) Cubic Law
According to the Cubic Law, fracture is formed by the smooth, flat, infinite long parallel plates without filling medium, and the water flow between the plates is viscous incompressible flow which is permanent laminar flow. Thus, according to the basic principle of fluid mechanics, the discharge per unit width through the crack surface i.e. q can be calculated by the follow formula:

$$q = \frac{\gamma \cdot a^3}{12 \cdot \mu} \cdot J_f \quad (4)$$

where, a is the breadth fracture; γ is the liquid unit weight; μ is the flow dynamics viscous coefficient of water; J_f is the hydraulic slope along the direction of fracture surface. According to Darcy Law, the above formula is formed as follows:

$$u = k \cdot J_f; \quad k = \frac{g \cdot a^2}{(12 \cdot \mu)} \quad (5)$$

where, g is the gravity acceleration.

c) Experience formula
Nolte show after test that if the mechanical gap width a_m replaces the crack width a, then the Cubic Law will not stand, and established the following empirical formula through the flow capacity test of fractures under the different normal stress action:

$$q = q_0 + C(a_m)^p; \quad a_m = a_{\max} - a_0 \quad (6)$$

Where, $a_{\max}$ is the closed maximum degree of fracture; a_0 is the compression value of fracture under the stress action; q_0 is the basic flow value of fracture when produced the greatest compression; C is constant.

Nolte concluded that the p value is about equal to 8 by test using quartz-feldspar fracture. Consequently, the empirical formula of seepage coefficient as follows according to Nolte experimental formula:

$$k = \frac{g \cdot a_m^{(p-1)}}{12 \cdot \mu} \quad (7)$$

d) Seepage coefficients influenced by mining
Louis established the following empirical formula of the relationship between the normal stress α and the permeability coefficient k of rock according to some pressure water test's result of drillings:

$$k = k_0 \cdot k_m \cdot e^{-\alpha \cdot \sigma} \quad (8)$$

where, k_0 is the initial permeability coefficient; k_m is the influence coefficient by mining (To take 5 to 10 in the long-wall working face, and take 10 to 15 in the short-wall face); α is the correction coefficient of mining in the shallow coal seam, takes 0.001 to 0.01; σ is the normal stress ($\sigma = \gamma h$), MPa; γ is the rock density, kN/m^3; h is the depth, m. According to the relation between the seepage and stress, permeability coefficient of overlying strata can be calculated after mining in the long-wall working face, see Table 2.

Table 2. The permeability coefficient expectation of overlying strata above long-wall face.

Zhiruo group	0.055	15	9.082	9.000	8.920	8.840
Yanan group	0.025	15	4.587	4.546	4.505	4.465

e) Measurement data
According to the field geological data of the detailed survey, it is known that the aquifer thickness of surface loosed strata in Shendong Mine Area is commonly between 0 m to 20.0 m. The buried depth of phreatic water is about 6.73 m to 10.17 m; the water hydraulic gradients changes greatly between 0.12 m to 13.92 m, and its average is about 10.0 m. The local hydraulic equivalent line is as shown in Figure 2.

The permeability coefficient of Jurassic Zhiruo group is 0.0535 m/d; and the permeability coefficient of No. 5 sect of Yanan group is 0.0253 m/d.

f) To estimate the seepage speed
Based on the above theoretical analysis and measured data and Turbulence Flow Law, we estimate the seepage speed of bedrock and weathered strata as follows by considering safety coefficient k_s (to take 1 to 5), see Table 3 and Table 4.

g) To estimate the seepage time after mining
Passing progress of phreatic water from fracture zone to the goaf after passed the water-resisting layer of weathered zone is very short and quickly. So, the seepage time can be approximately equal to the time through weathered zone strata and origin strata without fracture. According to the measured data, the height of fracture zones above long-wall face of shallow coal seam is commonly 45 m or so, when the mining height is taken 5 m to 6 m in Shendong Mine Area now.

Consequently, we may calculate the phreatic water's seepage time of aquifer-protective mining condition's each class according to the seepage speed of Table 4 by taking 45 MPa as the comprehensive strength of overlying strata, and see Table 5 and Table 6.

3.2 *To calculate the broken distance of key strata*

a) The initial broken distance
Based on the key strata theory, the calculation formula for initial broken distance L_c of roof key layer according to mechanics model of fixed supported girder is as follows:

$$L_c = h\sqrt{\frac{2R_t(1-\psi)}{q}};\quad q = \frac{E_1 h_1^3 \sum_{i=1}^{n}\gamma_i h_i}{\sum_{i=1}^{n} E_i h_i^3} \tag{9}$$

where, q is the weight of key strata and above strata; ψ is the mining damage factor of key strata (its value ranges from 0.1 to 0.5, here is 0.4 according to numerical simulation result); R_t is the available extension strength of key strata (σ_c); E_i is the elastic modulus of No. i layer strata, MPa; h_i is the thickness of No. i layer strata, m; γ is the bulk forces of No.i layer strata, kN/m^3; n is the number of restrained overlying strata by key layer (synchronization deformation to key layer). The calculation parameters are seen in Table 7.

b) The periodic broken distance

The major damage in the form of key layer strata is tension destroy. The fracture position in advance of key layer strata just is the position of immediate roofs periodic broken. So the periodic broken distance of key layer strata can be defined. The periodic broken distance L_z of key layer is calculated by the following formula according to the theory of half infinite long girder on the elastic foundation:

$$L_z = l_z + \frac{1}{\omega}\arctan\left(\frac{2}{3\cdot\omega\cdot l_z + 2}\right) \tag{10}$$

where, L_Z is the suspended stretch length of key layer, can be calculated by the following equation:

$$3\cdot q_1\cdot l_z\cdot e^{-\frac{\omega}{\sqrt{2}}x_1}\left(\frac{2\sqrt{2}+\omega\cdot l_1}{\omega}\sin\frac{\omega}{\sqrt{2}}x_1 + l_1\cos\frac{\omega}{\sqrt{2}}x_1\right) - h_1^2\cdot\sigma_c = 0$$

$$x_1 = \frac{\sqrt{2}}{\omega}\arctan\frac{\sqrt{2}}{\sqrt{2}+\omega\cdot l} \tag{11}$$

c) To calculate the broken distance of key layer above shallow coal seam

From the above formula, we select four models (Table 8) to calculate.

According to the related parameters of each stratum, the first and periodic broken distance of key layer strata of different strength and thickness are calculated, such as Table 9 shows.

From the Table 9, the periodic broken distance of key layer strata is general 21 m to 28 m, and the initial broken distance is about 50 m to

VII	Mining room is disposed in a single decorated form, and the aim of mining at no falling down of roof		

60 m, under the condition that the strength of overlying strata is 35 MPa, and the thickness of key layer strata is 10 m to 15 m.

3.3 *To determine the mining speed of each class*

The mining speed of long-wall face is major relevant to the length of working face and cutting speed. And the mining speed of short-wall face is major relevant to such factors as the length of working face, the cutting mode and the granularity of mining rooms.

According to the above calculation of the seepage time and key layer strata's periodic broken distance, the relevant mining speed of each class is calculated, and the results is listed in Table 10.

3.4 *To determine the range of working face length by the mining speed*

In order to aquifer-protective mining, the working face's length of each class is calculated by the following formula:

$$L_{face} \le \left(t_{work} \cdot v_{cut} \cdot d_{cut}\right) / v_{face} \tag{12}$$

where, L_{face} is the length of working face, m; t_{work} is the working time of working face each day; v_{cut} is the cutting speed of combine, m/h; d_{cut} is the cutting distance of combine, m; v_{face} is the advancing speed of working face, m/d.

The cutting speed of combine of long-wall working face in Shendong Mine Area is chosen 480 m/h, and the cutting distance is chosen 0.86 m. For short-wall face, it is equivalent to 15 m/h to 20 m/h of cut-ting speed, 10 m of cutting distance that the cutting speed of continued mining machine is 7.6 m/min, and 3 to 4 mining rooms is mining in one hour considering the preparing time. Consequently, the working face length of each class may be calculated as Table 11.

Table 11. The corresponding working face's length and speed of each class.

Sort	Advancing speed (m/d)	Upper limit of working face's length (m)
I	<10	
II	>10	750
III	>15	500
IV	>25	300
V	>35	80~100
VI	>45	60~80
VII	Mining room is disposed in a single decorated form, and the aim of mining at no falling down of roof	

4 CONCLUSIONS

Based on the mechanism and key of aquifer-protective mining, we put forward the idea that the working face's advancing speed is decided by the seepage velocity of water through the overlying strata, i.e. the time of working face's pass through the initial and periodic broken distance is less than the time of the above water seepage to working face. This time of long-wall general is 10 m/d to 15 m/d, and must be more than 25 m/d at the difficulty of aquifer-protective mining.

The length range of the safety aquifer-protective mining face has been determined by the lower limit of working face's advancing speed and the cutting speed of combine. Long-wall working face may be more than 300 m, and short wall working face generally is not more than 100 m.

The design of rapid prediction system on coal seam gas content

Yong-Tao Liu, Jia Liu, Shang-Quan Ma & Wei Di
North China Institute of Science and Technology, Lang Fang, Hebei Province, China

ABSTRACT: In this paper, coal seam gas content forecast needs to test and analyse the gas content of the coal sample. Gas desorption rate of coal sample gradually reduced with time extension, so we need to use a very low pressure loss of the gas flow sensor for testing. In order to adapt to the demand, the instrument design uses micro electro mechanical system (MEMS) flow sensor FS4001, to realize the collection of gas flow through the mixed signal processor 12 bit A/D conversion. According to coal sample gas desorption power function relationship between the rate changing over time, automatic matching is deduced under the natural state sample total coal desorption of gas. This instrument has realized the data acquisition, storage of more groups, curve display, time setting, desorption rate total logic deduction, the loss in fitting and so on in the field of micro gas measurement with its good application prospect.

Keywords: MEMS, flow sensor, curve fitting, least square method

1 INTRODUCTION

How to quickly and accurately determine the coal seam primitive gas content, is a topic on research field of coal mine gas prevention and control. Coal seam gas content is the basis to determine the gas emission data, is one of the important parameters of designing mine gas drainage and mine ventilation. The existing measuring equipment's function is not complete and it's intelligent degree is not high, so there is an important theoretical significance and practical value to design and develop a high performance of coal seam gas content tester (QI Li-ming 2007).

This article mainly introduce based on micro electro mechanical system (MEMS) flow sensor FS4001-200—CV—CH4 desorption of gas in coal bed recorder in the research and design method. For trace, low pressure loss and the volume of a gas flow velocity measurement.

The PC software design, using VC++ to program development, completed the linear fitting based on nonlinear least squares curve fitting and design, thus made further precise calculation and post-processing on lower machine data.

2 EXPERIMENTAL PRINCIPLES AND METHODS

2.1 *Basic principles of gas flow sensor FS4001-200—CV—CH4*

FS4001 is an application of micro electro mechanical system (MEMS) sensor chip technology, silicon chips use mechanical and electrical characteristics of micro-scale thermal film type sensor. It is not simply to miniature mechanical and electrical function on a chip, but adopt the modern materials technology and large scale integrated circuit technology combined with access to new features. MEMS chips can be obtained by some micro mechanical and electrical devices that cannot achieve the effect.

Hot membrane type gas flow sensor is made by using the principle of heat conduction and heat dissipation. Sensor adopts thermal quality gas flow sensor chip, belongs to the mass flow sensor of flowmeter. It measures the gas flow by gas flow field changes through the produced heat. The variation and the fluid velocity, heating current, surface temperature of the hot film, from these relations can be derived thermal membrane retention of heat Q and the relationship between the fluid velocity v (Sang Xiaowei 2009). Due to different quality of the gas changes have different impacts on the thermal field, as a result, the sensor measured by the flow of mass flow rate, and therefore there is no need to compensate temperature and pressure. At the same time, the adoption of multiple sensors, and micro heat source technology, make it have the excellent zero point stability, short response time and low loss characteristics (Li Caichun 2009; Fujita H 1995).

Unlike other MEMS sensor technology, FS4001 chip integrate a multiple of sensors on a single sensor. Chip surface adopted passivation of ceramic material with high thermal conductivity, in guarantee the sensor has a minimum of traffic at the

same time to avoid direct contact with the sensor and gas medium to improve its reliability. When there is no gas medium through the MEMS sensor chips, sensors keep a stable temperature field (distribution of temperature) around. When gas medium flows through the sensor, because of the fluid medium taking away heat, the temperature field leads a local temperature distribution (Wu Y 1992; Toda K 1996). Measuring principle is shown in Figure 1.

The local temperature field depends on the quality and velocity of fluid medium, integrates on a chip of the sensor to measure temperature distribution through calibration. The specially designed signal processing circuit will be converted to mass velocity and mass flow rate of medium into a linear relationship between output voltage value (Durst F 2003).

2.2 *Research of prediction system's function*

The gas content data recorder was designed with a scientific desorption method, desorption steps method is to use the common coal core tube coal core drill, when the coal core is putting forward after the orifice, then use the tank to seal the acquisition of coal sample containing gas, sample desorption instrument has been applied to the determination of coal gas desorption quantity law changing over time, and according to the exposure time of coal sample calculated the sampling gas quantity loss in the process. Then sent sample coal seal whose desorption law has been measured to the lab, determinate the residual gas content in coal core. After adjustment for temperature and pressure, with desorption gas quantity (including desorption quantity and loss quantity) and the sum of residual gas volume. Divided by the weight of coal core, the gas content of coal are obtained. The method for determining coal bed gas content adapt to take in geological exploration drilling coal core determination of coal seam gas content and gas composition.

Concrete steps as follows: first of all from coal seam drilling and sampling by coal core pipe, coal sample gas content including gas analytic data before crushing (measurement process for the first time, this process needs to measure before crushing coal sample methane desorption gas quantity Q_2, Q_1 and the loss) and crush after desorption data (second determination process, determination of the process after crushing the gas desorption quantity Q_3). The desorption rate of Q_2 meets regular pattern as shown in Figure 2, system makes use of these data using the following formula to fitting.

$$V_t = V_0 (1+t)^{-k} \tag{1}$$

In The Formula,

V_t – desorption rate of desorption gas at time t, ml/min;

k – constant;

V_0 – coal gas desorption rate at start ($t = 0$) desorption time, ml/min.

Then the processor according to the test data Q_2, where V_0 and fitting out the coefficient k, then generation back expression formula for V_t, according to the coefficient of the known formula exposure period of gas loss quantity Q_1. Last measured pieces begin to the end of the desorption time the total cumulative desorption volume in Q_3, When the desorption amount is less than 1 ml/min, instrument automatically end the Q_3 measurement, process and save the data.

The total gas content is calculated:

$Q_{content}$ – coal seam gas-bearing capacity, ml/g;

Q_1 – loss of gas quantity, ml;

Q_2 – desorption gas quantity before coal sample pieces, ml;

Q_3 – desorption gas after coal sample pieces, ml;

M – the total quality of the coal sample, g;

M_0 – pieces with the quality of the coal sample, g.

According to this formula, only the instrument keyboard input samples of coal sample total mass M and crushing coal quality M_0, can the total gas content Q always is deduced.

At the end of data processing, Q_1, Q_2, Q_3 and Q the total value can query and display at any time. Cumulative desorption rate desorption rate curve changes over time can query and display (Zhang Yanwen 1998).

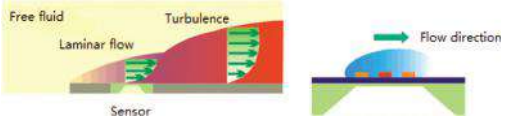

Figure 1. Sensor working principle diagram.

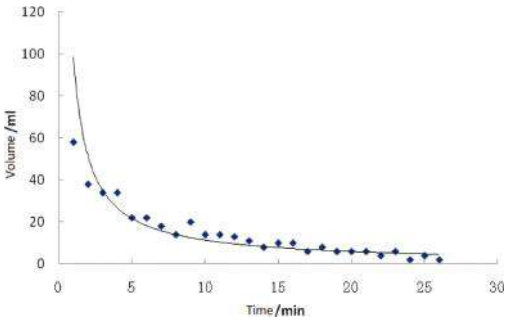

Figure 2. Desorption rate curve diagram.

2.3 *Under machine design*

The system uses MSP430F149 do give priority to the controller, cooperate with FS4001 gas mass flow sensor complete the gas content test. The whole function circuit includes MCU module, ferroelectric storage module, clock module, keyboard module, LCD display module, USB communication circuit module unit (Ji Liming 2010).

System uses the unit circuit design and has a high integration. This is to ensure the stability of the instrument, but also increases the difficulty of the system software design. The core and difficulty of the instrument design is that each point data of Q_2 fitting the curve of the value of Q_1 and Q_2 desorption rate being derived.

Due to the processor's operation limited ability, Q_1 data fitting process cannot use all Q_2 value to accurately fitting the Q_1 numbers. So system adopted nearby principle, according to the initial point of three numbers to the power function $V_t = V_0(1+t)^{-k}$ make a list of equations. Calculate starting rate V_0 and time constant k, again make t equal to 1, 2, 3 respectively where V_0 into the formula. Finally obtaining data values V_1, V_2, V_3, which is deduced from Q_1 result.

System programming difficulty and core focus on the LCD display curve fitting, data fitting and menu interface design.

2.4 *Experiment data comparison*

The group data, by one machine to the USB port to PC intelligent gas content prediction system. Run the PC software, set the COM port and baud rate, input to upload data from the instrument category, run the upload menu. PC interface is shown in Figure 3.

Software adopted two methods of data fitting processing, traditional curve fitting and nonlinear least square fitting. Through the test of the two methods, multiple linear regression coefficient was 0.991308 and 0.988942, respectively, the resulting fitting error controlled within 2%. After the treatment in choosing a good similarity, input the value of the specific test points number and M, M_0 data make a process for our needed results and saved to the database. Measurement data for Q_2 and fitting data Q_1 can be derived through the first interface, curve distribution can be copied or printed directly.

In view the data interface, data query process can be set according to place, time, total Q threshold alone or integrated query. We need to research and analysis of data directly to the graphics print or export to excel spreadsheet. As exporting data shown in Figure 4, including 1 fitting for piecewise curve fitting of data, 2 fitting for the least squares fitting of curve data.

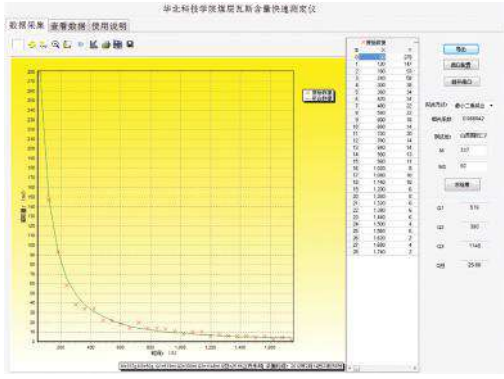

Figure 3. PC data fitting processing interface.

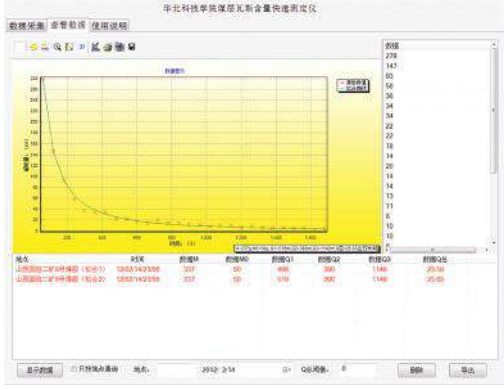

Figure 4. Data query interface.

3 CONCLUSION

Design of the instrument has features of small volume, light weight and good timeliness. When the gas desorption quantity is less than 1 ml/min the design can automatically complete the data processing, there's no need for staff to intervene to realize the intelligent operation of the equipment. The system reduces power consumption through a variety of software and hardware optimization, so it can meet for a long time, more group testing. Instrument connected to the computer through USB ports and the data transfer is accurate, stable and easy to operate. Design to the existing instrument can't display curve, can't direct the logic of the fitting, and derive the total gas desorption quantity shortcomings and so on has carried on the research and improvement. The successful design of the instrument to the underground coal seam gas content provides a good scientific method for fast measurement and support.

Research and application of technique of injecting liquid CO_2 in goaf of Shigang coal mine to preventing fire

Xin-Long Tong, Zhi-An Huang, Ying-Hua Zhang, Yan-Feng Zhang & Xin-Tong Wang
State Key Laboratory of High-Efficient Mining and Safety of Metal Mines, University of Science and Technology Beijing, Ministry of Education, Beijing, China

ABSTRACT: The extinguishing effect of liquid CO_2 is significant, but fire preventing technology with liquid CO_2 is not mature in coal mines. Against characteristics and laws of spontaneous combustion of residual coal in goaf, mechanism of preventing and extinguishing fire with liquid CO_2 was analyzed. Through carrying out temperature programmed experiments on coal samples, concentration and producing rate of CO, oxygen concentration and consuming rate of oxygen and other relating parameters under conditions of pure air and different concentrations of CO_2 were compared and analyzed. According to fire preventing theory and technology with liquid CO_2, combining with the actual situation of 15109 fully mechanized caving face of Shigang mine, a reasonable fire preventing system of injecting liquid CO_2 into goaf was built up, and then changes of gases and temperature in goaf were continuously monitored. Results show that liquid CO_2 has remarkable effect on fire prevention, and the system of injecting liquid CO_2 runs well, which prove that the proposed fire preventing technology has certain reference value to similar mines.

1 INTRODUCTION

According to statistics, as one kind of major energy in China, coal accounts for more than 85% of amount of domestic production and consumption of primary energy, so it occupies an important place in national energy structure. However, spontaneous combustion of coal has been so serious that it threatens safety production of mines heavily, and it has been such a major scientific challenge that it has not been completely resolved by any country until now.

As a kind of inert material, CO_2 has been widely used for prevention of various fire disasters, and it can control even extinguish various fire disasters in a very short period of time. It has so many advantages such as strong fire-fighting capability, short fire-fighting time, wide fire-fighting range, low pollution to environment and so forth, so it has been the first choice for dealing with various ground fire disasters. As technology constantly develops, CO_2 has been also applied for preventing fire in coal seam, and good effects have been achieved, but due to existing problems in fields of storage, transportation, cost and crafts, it still cannot be applied widely like nitrogen (Li 1998). In recent years, as storing technology of liquid CO_2 becomes mature, liquid CO_2 has been applied for dealing with various ground fire disasters more and more widely. Some mines at home and abroad have tried to apply liquid CO_2 to control Fire District, and fire extinguishing effects of liquid CO_2 have been remarkable, but research on adopting liquid CO_2 for preventing and extinguishing fire is still very limited, leading to immature of this technology.

The environment of spontaneous combustion of coal in goaf of mechanized caving face was analyzed, and technique of injecting liquid CO_2 into goaf to prevent and extinguish fire was studied, aiming to effectively prevent occurrence of spontaneous combustion of coal in goaf.

2 ANALYSIS OF ENVIRONMENT OF SPONTANEOUS COMBUSTION OF COAL IN GOAF AND MECHANISM OF PREVENTING AND EXTINGUISHING FIRE WITH LIQUID CO_2

Spontaneous combustion of coal starts at physical adsorption of oxygen which provides energy for coal-oxygen chemisorptions by releasing heat. Coal is a kind of natural adsorbent, being able to absorb inorganic substances such as CH_4, CO_2, N_2 and organic substances such as methanol and benzene (H 2002). Adsorbing capacities and speeds of coal against different substances are different. According to soluble mechanism, gas with higher boiling point and critical temperature can more easily spread into all pores of coal, and can be more easily absorbed by coal. Boiling points and critical temperatures of four gases which are CO_2, CH_4, CO and N_2 are shown in Table 1.

Capacity and speed of coal adsorbing CO_2 are all better than coal adsorbing other gases. Quantum

Table 1. Boiling points and critical temperatures of four gases.

Gas	CO_2	CH_4	CO	N_2
Critical temperature/K	304.2	191.1	132.8	126.2
Boiling point/K	194.7	109.2	81.5	77.4

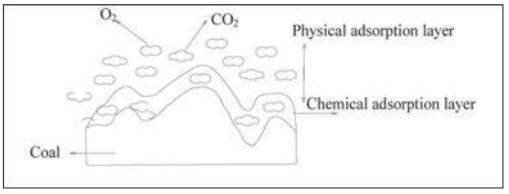

Figure 1. Schematic diagram of CO_2 inhibiting coal-oxygen physical adsorption.

chemical study on interaction between coal surface and CO_2 has shown that coal adsorbing CO_2 is physical adsorption which can be multilayer adsorption and relatively stable (Cui 2005, Jiang 2006). When coal surface needs to adsorb gas molecules, CO_2 molecules can be stably adsorbed on surface of coal sooner than oxygen molecules. Therefore, when there are a variety of gases at the same time underground, CO_2 can be quickly adsorbed by coal, wrapping coal body and preventing oxygen from contacting coal, so spontaneous combustion of coal can be inhibited (Liu 2006).

Schematic diagram of CO_2 inhibiting coal-oxygen physical adsorption is shown in Fig. 1.

As a kind of inert material, once injected into fire preventing area, CO_2 can evaporate and then spread to fill space rapidly, driving O_2 in hazardous areas to make the Fire District suffocate as result of lacking oxygen or inhibit spontaneous combustion of coal. Steaming of liquid CO_2 needs to absorb large quantities of heat, which make temperature in dangerous area decrease. Except the general role of preventing fire of inert gas, liquid CO_2 has its unique fire preventing characteristic such as wide cooling range, obvious effect, high inerting speed and great perfusion flow (Han 2009).

Liquid carbon dioxide achieves fire-fighting purposes by following three ways (Zhao 2010):

1. Effect of separating oxygen and covering. Spontaneous combustion of coal is result of coal-oxygen compounding reaction, as oxygen is a necessary condition of oxidation reaction. If there is no oxygen or only little oxygen, spontaneous oxidation of the coal would be interrupted or inhibited.
2. Effect of cooling and lowering the temperature. Liquid CO_2 can quickly cool off high temperature coal body and suppress temperature of coal rising, so spontaneous combustion of coal can be prevented.
3. Effect of inerting and suppressing explosion. Vaporizing CO_2 can dilute content of combustible gas and oxygen and make degree of inerting of gases in space of Fire District become larger and larger, which can hinder formation of activation center and make explosive gas reflect inerting explosive characteristic.

3 EXPERIMENTAL RESEARCH OF LIQUID CO_2 AFFECTING SPONTANEOUS COMBUSTION OF COAL

When heat released by coal-oxygen chemical reaction is more than distributing heat, temperature of coal rises and causes fire, so spontaneous combustion of coal can happen (Deng 2003). This process was simulated under experimental condition, and through injecting liquid CO_2, changing laws of coal's temperature, oxygen consuming amount, CO producing amount as well as relating parameters of other gases during this process were all studied. Experimental conditions were as follows:

1. Quality of samples are 1.0 kg, which was got by crushing and sieving raw coal and taking 20 g of coal particles with granularity of following ranges: 0~0.9 mm, 0.9~3 mm, 3~5 mm, 5~7 mm, 7~10 mm;
2. Heating rate: 0.5 °C/min (room temperature to 110 °C); 1 °C/min (110~210 °C); 2 °C/min (210~330 °C);
3. Liquid CO_2 injecting frequency was every time temperature rising 20 °C;
4. Liquid CO_2 injecting volume was 100 ml/min, as concentrations of CO_2 were respectively 9%, 17%, 25%, and 38%. Different concentrations of liquid CO_2 were injected into different coal samples, and then temperature-programmed experiments were carried out. Four groups of coal samples from least to most of concentration of liquid CO_2 injected were respectively numbered 1#, 2#, 3# and 4#, and the group of coal samples not injected liquid CO_2 was numbered 5#.

Schematic diagram of experimental apparatus is shown in Fig. 2, and curves of concentration of O_2, CO and CH_4 changing with temperature are respectively shown in Fig. 3–Fig. 5.

According to Fig. 3, through comparing and analyzing curves of concentration of O_2 changing with temperature, what can be known are as follows: CO_2 has great influence on concentration of O_2, and concentration of O_2 of coal samples under condition of pure air is larger than that of coal samples injected CO_2. As temperature rises, concentration of

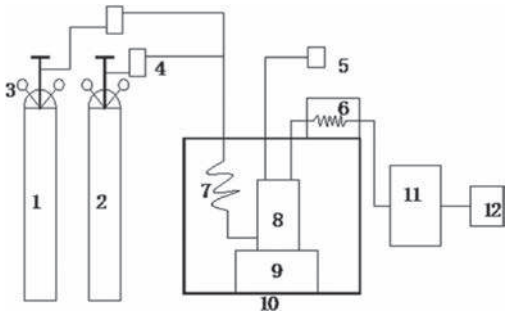

Figure 2. Schematic diagram of experimental apparatus.

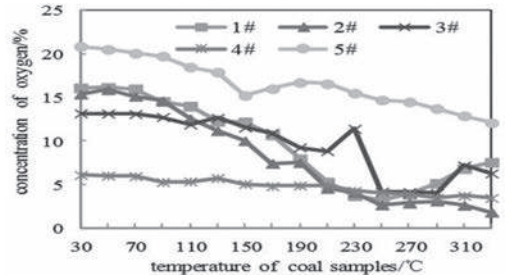

Figure 3. Schematic diagram of experimental apparatus.

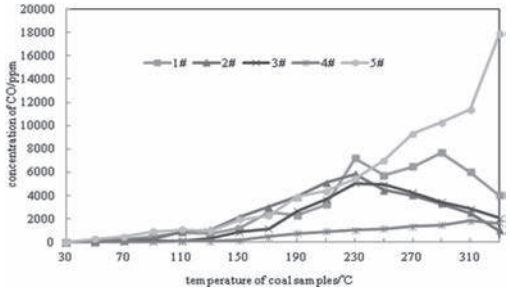

Figure 4. Curves of concentration of CO changing with temperature.

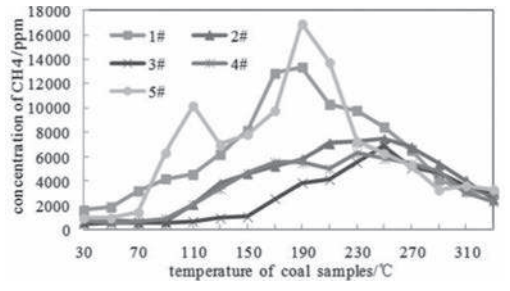

Figure 5. Curves of concentration of CH_4 changing with temperature.

O_2 decreases. Coal-oxygen oxidation reaction weakens and eventually stops due to lacking oxygen.

According to Fig. 4, through comparing and analyzing curves of concentration of CO changing with temperature, what can be known are as follows: as temperature rises, concentration of CO of each group of coal samples increases. Curves of concentration of CO of coal samples injected liquid CO_2 are all lower than that of raw coal samples, and with concentration of liquid CO_2 injected increasing, these differences become more obvious, which proves that Coal-oxygen oxidation reaction increases as temperature rises concentration of CO produced by oxidation of 1# ~ 4# coal samples are less than that of raw coal samples under influence of CO_2.

According to Fig. 5, through comparing and analyzing curves of concentration of CH_4 changing with temperature, what can be known are as follows: in temperature range of 130 °C~330 °C, CH_4 is produced by pyrolysis of coal which only has something to do with temperature, CH_4 produced by 5# coal samples is far more than that produced by other groups of samples, which proves that in high temperature range, CO_2 can significantly reduce methane producing amount and can inhibit coal producing CH_4 by oxidation pyrolysis.

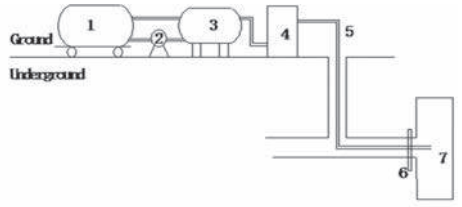
4 EXPERIMENTAL RESEARCH ON THE TECHNIQUE OF INJECTING LIQUID CO_2 INTO GOAF OF SHIGANG MINE FOR PREVENTING FIRE DISASTER

4.1 *Overview of mine and mining face*

Shanxi Shigang Coal Mine has field area of about 7.479 square kilometers, and its recoverable reserves is 31 million tons.

The experiment mining face is NO.15109 mining face which lies at NO.1 mining area. Its trending length is 560 m, incline length is 157 m, and area is about 87250 m^2. Its coal seam has stable occurrence and complex structure, with maximum, minimum and average total thickness being respectively 7.73 m, 6.85 m and 7.23 m. There are generally two layers of rock in the coal seam, as one layer with thickness 0.28 m lies at position where is 2.36 m below roof and the other layer with thickness 0.35 m lies at position where is 0.47 m above backplane. There are joints developing in the coal seam.

4.2 *Injecting process of liquid CO_2*



According to actual situation and environmental conditions of NO.15109 mining face of Shigang coal mine, considering cost and other relating factors, method of vaporization perfusion from ground was adopted, that is to say, liquid CO_2 is transported from chemical plant to mine by

specialized transport tank lorry and imported to low temperature storage tank, and then vaporized on the ground by external vaporizer, and finally transported to via pipeline to goaf or Fire District for fire prevention. Liquid CO_2 equipments are installed on ground near wellhead and connected to underground fire-fighting pipes so that a stationary fire-fighting system can be built up. The process map of injecting CO_2 is shown in Fig. 6.

4.3 *Arrangement of data acquisition system of injecting liquid CO_2*

Data acquisition includes gas sampling and temperature acquisition. Manual sampling method was adopted on purpose of saving cost. Temperature were measured by using TES-1310 digital thermometer, compensation wire with indexing number KC and K(CA)NiCr/NiAI thermocouple and data then was recorded. Gas samples were carried back to ground and analyzed with chromatograph.

Data acquisition system was arranged at return airway of 15109 mining face, and spacing of measuring points was 70 m. The first measuring point is 5 m away from the front of initial releasing mouth. Method of burying pipes for observation was adopted, as three beam tubes and three survey lines were buried at bottom of right side ditch of 15109 mining face, and two-inch steel pipe was used as their protective casing. A temperature probe and a beam tube dust filter were set up at each measuring point. The schematic diagram of arrangement of measuring points is shown in Fig. 7.

1 - liquid CO_2 tank lorry, 2 - booster pump, 3 - low temperature storage tank, 4 - carburetor, 5 - injecting pipeline,6 - closed wall, 7 - goaf

Figure 6. Process map of injecting CO_2.

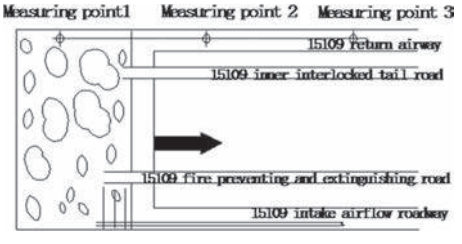


Figure 7. A schematic diagram of arrangement of measuring points.

4.4 *Monitoring and analysis of experimental effect of injecting liquid CO_2*

4.4.1 *Changes of gas concentration and temperature in goaf of 15109 mining face*

When 1 # measuring point is 35 m away from the mining face, namely injecting mouth is 30 m away from the mining face, liquid CO_2 was begun to be injected continually. In order to better monitor and analyze fire preventing effect of injecting liquid CO_2 into goaf and grasp change of gas concentration in goaf and distributing law of the three zones, temperature was measured and gas samples were analyzed continually for three months at the three measuring points at air returning side of goaf.

Changes of concentration of CO, CO_2 and O_2 at air returning side of goaf in situation of continuous injection are respectively shown in Fig. 8–Fig. 10.

As Fig. 8 shows, before injecting liquid CO_2, with the mining face advances, concentration of CO in goaf gradually increases, especially when distance between 1# measuring point and mining face is more than 30 m, concentration of CO rapidly increases, as maximum concentration reaches

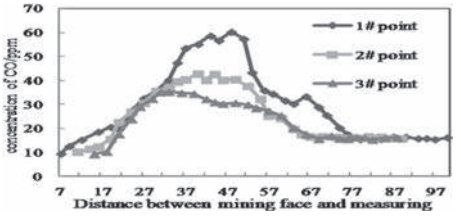

Figure 8. Change of concentration of CO.

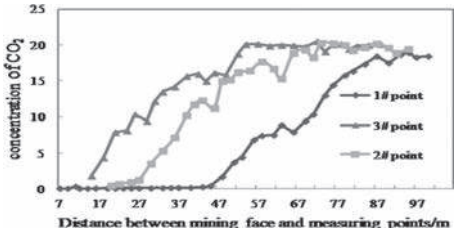

Figure 9. Change of concentration of CO_2.

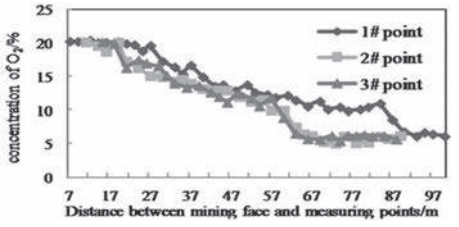

Figure 10. Change of concentration of O_2.

60 ppm. As liquid CO_2 is continuously injected, concentration of CO quickly decreases, and ultimately maintains at a low level, which shows that 1# measuring point quickly passes through oxidized spontaneous combustion zone and gets into choking zone. What can be seen from results of 2# and 3# measuring points is that under condition of continuously injecting liquid CO_2, concentration of CO at each measuring point all firstly increases a little but then decreases rapidly, finally maintains at low level of about 15%. Therefore, the inhibiting effect against spontaneous combustion of residual coal of continuously injecting liquid CO_2 in goaf is very good.

As Fig. 9 shows, after injecting liquid CO_2 in goaf, concentration of CO_2 in goaf significantly increases, as maximum concentration reaches more than 20%. When measuring points are relatively close to the mining face, concentration of CO_2 is relatively low, mainly because falling rock gap near the mining face is large and air leakage in goaf is serious as leakage flow can transfer and dilute CO_2. The nearer to the mining face, the larger the effect is. However, at position far away from the mining face, air leakage is little and concentration of CO_2 is relatively large. As depth of goaf increases, falling rocks are gradually compacted and transferring effect of CO_2 stream is inhibited, so concentration of CO_2 increases and finally reaches balanced state (Wang 2011).

As Fig. 10 shows, width of area where concentration of O_2 maintains in range of 10%~18% gradually shortens, and this kind of area advances a lot. That is to say, under condition of continuously injecting liquid CO_2, oxidized spontaneous combustion zone gradually shortens.

4.4.2 *Analysis of test results of gas concentration at the upper corner of 15109 mining face*

In order to ensure concentration of O_2 in 15109 mechanized caving face above safe value and prevent a large number of toxic and harmful gases from gushing out, gas concentration at the upper corner of 15109 mining face was continuously monitored for a month. Changes of concentration of O_2, CH_4, CO and CO_2 at the upper corner are respectively shown in Fig. 11–Fig. 14.

As can be seen from Fig. 11 to Fig. 14, continuous injection of liquid CO_2 has little influence on concentration of O_2 which basically maintain at about 20%, but it has greater influence on CO as concentration of CO decreases and finally maintains at about 5ppm, moreover, it has little influence on CH_4 as concentration of CH_4 only changes a little. After the injection, concentration of CO_2 increases and ultimately maintains at about 0.18%. Therefore, continuously injecting CO_2 into goaf is feasible and safe.

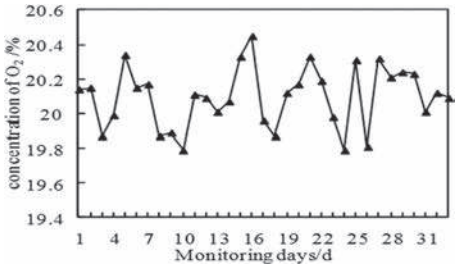

Figure 11. Change of concentration of O_2 at the upper corner.

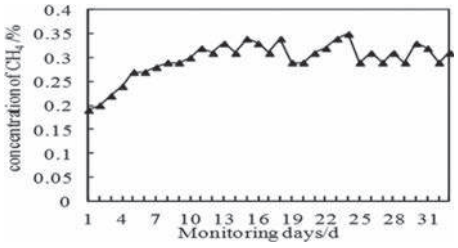

Figure 12. Change of concentration of CH_4 at the upper corner.

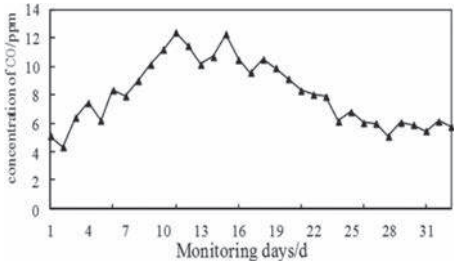

Figure 13. Change of concentration of CO at the upper corner.

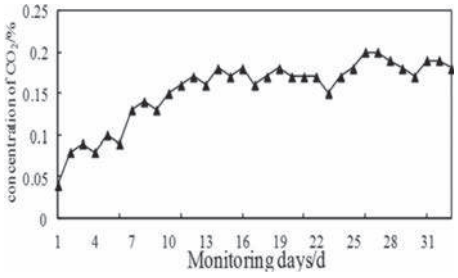

Figure 14. Change of concentration of CO_2 at the upper corner.

4.4.3 *Changes of three zones of spontaneous combustion in goaf*

Through analyzing change of concentration of O_2 in goaf, what can be known is that under condition of continuously injecting liquid CO_2, at

Table 2. Change of three zones of spontaneous combustion after injecting CO_2 into goaf of 15109 mining face.

Three zones	Heat dissipation zone	Oxidized spontaneous combustion zone	Choking zone
Concentration of O_2 /%	>18	10~18	10
Width of zone before injecting CO_2/m	30	30~87	>87
Width of zone after injecting CO_2/m	19	19~60	>60

position about 19 m away from the mining face, concentration of O_2 decreases to below 18% and oxidized spontaneous combustion zone is reached, and at position about 60 m away from the mining face, concentration of O_2 decreases to below 10% and choking zone is reached. Changes of three zones of spontaneous combustion after injecting CO_2 into goaf can be seen from Table 2. As Table 2 shows, after the injection, oxidized spontaneous combustion zone advances 11 m and shortens 16 m, and choking zone advances 27 m, which together prove that continuously injecting CO_2 into goaf has great inhibiting effect on spontaneous combustion of residual coal and good fire preventing effect.

4.4.4 *Analysis of effect of injecting liquid CO_2 into goaf*

In goaf of 15109 mining face of Shigang mine, through nearly three months of continuous monitoring, what can be known is that with amount of injection increasing, concentration of O_2 at each measuring point all decreases and ultimately maintains at about 6%, concentration of CO_2 maintains at about 20%, and temperature at deep position of goaf maintains at about 20 °C, moreover, concentration of CO maintains at relatively low level, which all together prove that the technique of injecting liquid CO_2 into goaf for fire prevention can effectively inhibit formation of hot spots in goaf and prevents coal spontaneous combustion of residual coal (Li 2008).

5 CONCLUSIONS

1. In addition to the general role of preventing fire of inert gas, liquid CO_2 has its unique fire preventing characteristic such as wide cooling range, obvious effect, high inerting speed and great perfusion flow. Its fire-fighting mechanism mainly reflects in the following three respects: effect of separating oxygen and covering, effect of cooling and lowering the temperature and effect of inerting and suppressing explosion.
2. Results of the temperature-programmed experiments show that CO_2 has good inerting effect on spontaneous combustion of coal, but it is easily influenced by concentration and ambient temperature. When concentration is over 20%, CO_2 has obviously inerting effect and the higher the temperature is, the stronger inerting effect is; moreover, CO_2 with low concentration has inerting effect in low-temperature stage, but its inerting effect in high-temperature stage is not obvious.
3. As CO_2 is injected continuously, concentration of O_2 at each measuring point all decreases and ultimately maintains at about 6%, concentration of CO_2 maintains at about 20%, and temperature at deep position of goaf maintains at about 20 °C, moreover, concentration of CO maintains at relatively low level, which all together prove that the technique of injecting liquid CO_2 into goaf for fire prevention can effectively inhibit formation of hot spots in goaf and prevents coal spontaneous combustion of residual coal.

Research on wind tunnel reducing ventilation resistance

Jing-Gang Zhang
Institute of Resource and Safety Engineering, China University of Mining and Technology (Beijing), Beijing, China
Key Laboratory of Mine Disaster Prevention and Control Technology in Hebei Province, China
College of Safety Engineering, North China Institute of Science and Technology, Beijing, China

ABSTRACT: Wind tunnel is defined to connect the main fan and shaft tunnel. Wind tunnel ventilation resistance has always been a big problem of mine ventilation resistance. This article analyses measured the ventilation resistance of many wind tunnels. Based on the theoretical analysis about reasons, it is concluded that there are many reasons contributing to a larger ventilation resistance, at the same time it puts forward the improvement to decrease the ventilation resistance, save energies and achieve good economic benefits.

1 INTRODUCTIONS

The wind tunnel is the connection of the main fan and shaft tunnel. Because of big ventilation quantity and pressure difference between inside and outside, it should try to reduce the ventilation resistance and reduce the air leakage. Though its short length, resistance loss often has accounted for more than 10%, some 50%, or even far more than mine design hypothesis of 200 Pa in the sinking and driving system (not including wind tunnel). As far as possible measures are required taking to reduce the ventilation resistance in the design, construction and use of wind tunnel. According to the requirements of the wind tunnel, ventilation resistance should be less than 0.0196 N.s^2/m^8, generally not more than 0.0490 N · s^2/m^8~0.0980 N · s^2/m^8.

2 THE CONDITION OF WIND TUNNEL VENTILATION RESISTANCE

In order to know wind tunnel well, we research and refer to the materials of 13 wind tunnels. Was found wind ventilation resistance of the mine situation what was found about ventilation resistance follow as in the table 1.

As known from Table 1:

1. As a result of different forms, construction qualities and management levels, the ventilation resistance R, resistance loss h, ventilation resistance of adit of sinking and driving system resistance percentage K value vary considerably. R varies from 0.016 N · s^2/m^8 to 1.232 N · s^2/m^8; K varies from 6.58 to 75.16%. (Cai Wei 2004)
2. Ventilation resistance of wind tunnel is greater than 0.0196 N · s^2/m^8, while 53.8% of the wind tunnels R are larger than 0.098 N · s^2/m^8 and R of three wind tunnels are larger than 0.294 N · s^2/m^8, the largest 1.232 N · s^2/m^8.
3. The ht of 50% of the wind tunnels researched in the survey is more than 200 Pa, the largest 1097.6 Pa.
4. The K of 76.9% of the wind tunnel researched in the survey is more than 10%, among which K of three wind tunnels is more than 50%, the largest one is 75.6%.

The data above show that quite a great part of output energy from some mine main fan is consumed in the wind tunnel, sometimes 50%. Ventilation resistance of many wind tunnels is larger than 0.0490 N · s^2/m^8~0.0980 N · s^2/m^8. Attention should be paid.

3 THE THEORETICAL ANALYSIS ON THE RESISTANCE OF WIND TUNNEL

3.1 *Analysis of friction resistance*

Friction resistance is produced due to mutual friction between air, shaft wall and air micelle when air flows along the tunnel. Its formula is:

$h_f = \frac{\alpha L U Q^2}{S^3}$ h the

In the formula: is refered as friction resistance, Pa; Q is referred as air volume through tunnel, m^3, L is referred as length of the air flowing through shaft, m; α coefficient of the friction resistance, N · s^2 / m^4; U section perimeter, m; h_t

We can adopt the following methods to reduce friction resistance of wind tunnel from above formula:

1. Reduce the coefficient of friction resistance α.
2. Guarantee enough sinking and driving section. As other parameters are constant, the area of sinking and driving section expands 33%, h_f can be reduced by 50%.

Table 1. Summary about ventilation resistance of the wind tunnel.

Mine fan system	The wind adit section S_t (m^2)	Wind speed V (m/s)	Air volume Q (m^3/s)	Mine resistance h_m (P_a)	Adit wind resistance h_t (P_a)	K = ht/h_m × 100 (%)	Wind tunnel resistance Rt (N . s^2/m^8)
1	7.66	9.5	72.8	940.8	138.1	14.68	0.026
2	2.2	10.2	22.6	217.5	19.6	9.09	0.038
3	3.39	4.38	14.9	363.5	272.7	75.6	1.232
4	5.95	10.1	60.1	815.3	242.0	29.66	0.067
5	5.6	11.3	63.3	216.5	284.2	13.12	0.070
6	2.8	18.5	52.0	379.2	196.0	51.68	0.072
7	4.75	9.5	45.3	1372	196.0	14.3	0.095
8	6.7	12.9	96.7	3067.4	1097.	35.78	0.117
9	4.0	16.4	65.6	1117.2	539.0	48.2	0.125

12	5.1	3.34	17.0	1430.8	94.0	6.58	0.325
13	2.39	7.6	18.2	519.4	117.6	22.6	0.352

3. Choose a sinking and driving which has a smaller perimeter. Under the condition that sinking and driving section is of the same area, the perimeter of the circular section is the minimum, while arch section fades to it, and the circumference of rectangular or trapezoidal section is the larger.
4. As far as possible to shorten the length of the wind tunnel.
5. Avoid wind too centralized in the tunnel.

3.2 *Analysis of local resistance*

Due to The cross section of mine, change of direction and bifurcation or convergence and so on, local resistance makes uniform flow in the local area affected and damaged, resulting changes in wind velocity field distribution and eddy current and so on, and causes the wind energy loss. Generally experience formula of local resistance is: $h_l = RLQ^2 = \frac{u_1^2 \xi_1 \rho}{2}$ or $RLQ^2 = \frac{u_2^2 \xi_2 \rho}{2}$ In the formula: ξ_1 is the average wind speed before air flow into local resistant objects; μ_1 is the coefficient of corresponding local resistance, dimensionless; ξ_2 is the average wind speed after air flow into local resistant objects; u_1 is the coefficient of corresponding local resistance, dimensionless; h_1 is for local resistance Pa.

4 THE ANALYSIS OF THE CAUSES OF THE LARGER VENTILATION RESISTANCE

Combining the wind tunnel involved in the survey and basic situations of wind tunnel, we analyse what increases ventilation resistance in the production, and then get the actual factors influencing ventilation resistance.

4.1 *Unreasonable construction form of wind tunnel*

The three basic forms of wind tunnel:

1. The oblique type (Figure 1): Between the return air shaft and fan there is 45°or so inclined lane connection. This form of wind tunnel adopts comparative gentle dip and reduces the resistance caused by turning. With a simple structure and the wind tunnel is very short, the ventilation resistance is relatively small. (Cheng Shaoren & Cheng Jianjun 2006).
2. The line type (Figure 2): due to the special geologies or design factors, we cannot use a plain tunnel to connect directly to the return air shaft, but have to use inclined tunnels with some sharp turnings and plain tunnels to compose wind tunnels. The ventilation resistance is greater by increasing the length of tunnel, setting nasty angle of inclined lane.
3. The vertical shaft type (Figure 3): due to the design or other causes, wind tunnel cannot adopt the up type, but connects a few plain tunnels (or inclined lanes) with return air shafts. The ventilation resistance of this type is large. The reason is there are many sharp turnings surely increasing the length between two points of tunnel and the defects in the tunnel design, water spray is bigger, and these reasons comprehensively lead to the large resistance of wind tunnel.

Above the analysis, we can conclude that the oblique type is the best construction form of wind

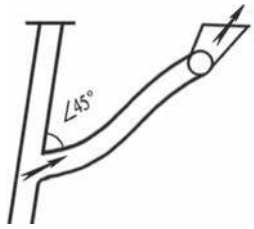

Figure 1. The oblique type.

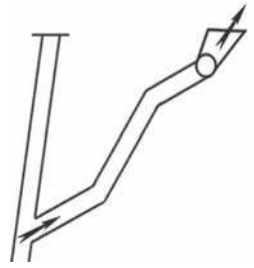

Figure 2. The line type.

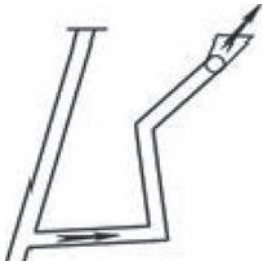

Figure 3. The shaft type.

tunnel, which has the minimum ventilation resistance, while shaft type is the worst and line type is medium.

4.2 *Unreasonable length and excessive turnings in designing wind tunnel*

In the practical production, unreasonable length of wind tunnel has a direct effect on the ventilation resistance. The unreasonable turns in the wind tunnel are caused by the unreasonable length.

Too many turnings directly lead to increase length of the wind tunnel; an elbow bend not only increases length of tunnel, but also increases ventilation resistance in the turning. The length of wind tunnel ranges generally from 35 m to 50 m, but some wind tunnels turn 2 or 3 elbow bends, causing a lot of local losses. Some of losses are from thoughtless designs, while some are caused by reconstructing old wind tunnels, others are because of contrary air flow directions between axial fan and wind shaft, artificially increase the ventilation resistance. Or not according to the design requirements to construct and artificially increase the number of turning, poor quality of construction cause large local ventilation resistance with rough and not gentle corners.

4.3 *Unreasonable design for wind tunnel section*

The wind tunnel section is so small that it results large wind velocity. The design of the wind tunnel is matched with power of a fan; it does not result in too large wind speed, which effects ventilation resistance.

4.4 *Unreasonable organization management for wind tunnel*

1. Laying multiple pipes and piling a lot of float coals cause to increase resistance of wind tunnel.
2. The air volume is not only that from the mine underground, but also all the air leakage. A large number of shaft head air leakage increase air volume of the wind tunnel and resistance. In addition, a large number of air leakages forming intersection of cold and warm air cause perennial water spray by in the wind tunnel and increase the ventilation resistance of the mine. (Cheng Genyin et al., 2009).

4.5 *For other reasons*

Due to the sudden changes in the connection of wind tunnel and wind shaft, larger local ventilation resistance is formed. Some wind tunnels inside may suddenly become larger or smaller. Unreasonable use of gate put in the wind tunnel regulating air cause the wind tunnel additional resistance.

5 MEASURES TO REDUCE VENTILATION RESISTANCE

5.1 *Design wind tunnels*

Other comprehensive factors should be considered when designing wind tunnel, the following terms about designing should be paid attention to:

1. Using Single oblique type to fit the layout of wind tunnel.
2. Wind tunnel is directly linked with the shaft together and tries to reduce the number of turning, which angle is less than sixty. All the connection corners should be smooth, especially the inside corner, which should be put into a double curves, we should use a sleek obtuse angle bend instead of an elbow bend.

3. Large enough section, which makes its wind speed less than 10 m/s and not more than 15 m/s, it is appropriate to use a round or close to a round section. (Wang Junliang et al., 2006).
4. The joint of wind tunnel and wind shaft should avoid a sudden narrow or expansion, within the range of wind tunnel, the areas with the different sections should have a gradual transition.
5. Trying to shorten the length of the wind tunnel as far as possible. (Xin Guanglong et al. 2004).
6. In the installation of main fan the centerline of wind tunnel is consistent with the axis of axial flow fan, and centrifugal fan must be vertical to axis.
7. Building it by lying bricks or stones and cement finishing wall, keep the surface neat and reduce the air leakage on the wind tunnel wall.
8. Getting rid of obstacles to keep air ways clear and make the total resistance of wind tunnel less than 200 Pa and l0% of total resistance of all mine ventilation system.

5.2 *Usage and management*

No special necessities, wind tunnel is not compatible for other purposes (such as laying pipes and cable, etc.). Often clear the tubes, stone, coal dust and debris inside the wind tunnel. Take effective measures to minimize the ground air leakage.

5.3 *Transform seriously unreasonable wind tunnel*

Some wind tunnels can adopt one or several measures to reduce the ventilation resistance. Wind tunnels affected negatively by a long length and too many quarter turns with large R_t, h_t, K must be transformed. (Zhu Kai et al., 2004).

Take the wind tunnel for example, before transforming it has a steel reinforced concrete structure and a rectangular cross-section, its specifications: width 2.0 m, height 2.1 m, section area is 4.2 m^2. To meet the requirements the area of wind tunnel section is expanded to at least 1.6 m^2. An air corridor (steel air duct) is added between reverse wind crossing of the centrifugal fan and the derrick of main shaft in the reconstruction design. To expand the wind tunnel section, we can parallel a new air way with the original wind tunnel. New air way has a square section (1.5 m *1.5 m) and steel plate (thickness is 10 mm). One end of it connects to the derrick of main shaft while the other end connects with the reverse wind crossing. The outlet is sealed with a 10 mm thick steel plate, then exit is cut in the junction, thus fresh air ways and two joint points are welded firmly. It is shown in the Figure 4. After transforming ventilation resistance of wind tunnel drops to 0.057 $N \cdot s^2/m^8$, resistance reduces 205.01 Pa, underground air volume increases by 9.33 m^3/s, thus further improving the condition of mine ventilation.

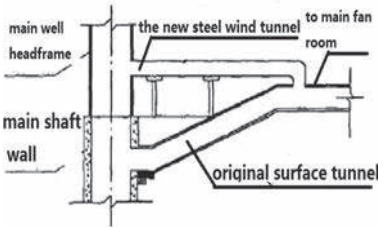

Figure 4. Wind tunnel reconstruction plans.

6 SUMMARIES

In conclusion, the output energy of the mine main ventilator is quite consumed in the wind tunnel; some may reach 50% or even more. There are many reasons contributing to it. Although ventilation resistance is usually very large, the benefit is very considerable as long as we take measures in the design, construction and reconstruction links to reduce the ventilation resistance. So it is not dispensable to reduce the ventilation resistance when it comes to developing ventilation potential, saving energy, and achieving good economic benefits. In some cases, it is expanding measures such as underground roadway with large range of influence, quantities less effective, fast, saving a lot of advantages of electrical energy. So to achieve the purpose of developing the scientific concept, it requires us flexible in the application and comprehensively developing.

Research on the application of controllable circulatory ventilation in the mine

Jing-Gang Zhang
Key Laboratory of Mine Disaster Prevention and Control Technology in Hebei Province, China
Institute of Resource and Safety Engineering, China University of Mining and Technology (Beijing), Beijing, China
College of Safety Engineering, North China Institute of Science and Technology, Beijing, China

ABSTRACT: This paper focuses on the analysis of the controllable circulatory ventilation technology which is a new economical and practical ventilation technology. It can effectively solve the problem of partial air supply shortage in the large mine caused by the over-large production layout. According to Lizhuang Coal Mine's condition, I have analyzed its ventilation's problems. I think we can apply the controllable circulatory ventilation to this mine. In this paper I also propose three implemental projects, choose the most suitable one after the analysis and compare and put forward the security technology measures that should be noticed in the use of the controllable circulatory ventilation.

1 CONTROLLABLE CIRCULATORY VENTILATION

1.1 *Definition of controllable circulatory ventilation*

Controllable circulatory ventilation system is a new technology developed with the need of tunneling and recovery safety of ventilation. When conventional methods cannot solve the problem or are economically unreasonable, the controllable circulatory ventilation technology is a good choice. It can increase air flow, improve the climate conditions and save ventilation cost. As it is showed in Figure1.1, controllable circulatory ventilation system refers that we can control part of air flow artificially letting them flow through the same place many times and be used repeatedly. The word "controllable" has two meanings: There should be impetus to provide energy. Let artificially some backed air flow into the intake airway and be mixed with fresh air; Control the amount of the circulated air and make sure the mine gas density in the mixed intake air and return current is less than that in the Rules of Coal Mine' Safety. Its method is setting a ventilation fan between the intake air and the return current or in the inside of the airs. Thus the return current can cycle and the ventilation fan is called gas circulator.

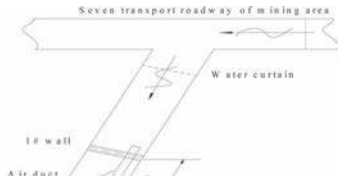

Figure 1. Controllable circulatory ventilation system.

1.2 *Circulatory ventilation system and its features*

Take the lane linking intake airway and return current way as the circulation duct and install a gas circulator. In the figure1.1 the area of 5-2 is the circulated area. Circulation rate F refers to the ratio between the circulate wind and the actual air volume in the work face. That is $F = Q_{5-2}/Q_{3-4}$. The figure F reflects the circulated levels of the airflow. Assuming the mine gas Q_1 (m^3/s) in the area comes from the work face, the volume of the fresh air Q_1 in the work face does not change with the airflow's circulation. There is not mine gas in the fresh air and compared with the airflow's volume Q_1, the mine gas' discharged volume q1 is very small. According to the relevant formula, every branched air flow and gas concentration in steady state are:

Air-intake shaft in work face:

$$Q_{2\text{-}3} = Q_1/(1-F) \quad \rho_{2\text{-}3} = F \times (q_1/Q_1)$$

Airs return way in work face:

$$Q_{4\text{-}5} = Q_1/(1\text{-}F) \quad \rho_{4\text{-}5} = q_1/Q1$$

Circulation duct:

$$Q_{5\text{-}2} = Q_1 \times F/(1-F) \quad \rho_{5\text{-}2} = q_1/Q_1$$

Airs return way in the system:

$$Q_{5\text{-}6} = Q_1 \quad \rho_{5\text{-}6} = q_1/Q_1$$

From the above formulas we can know that except for mine gas density in the intake airway in the work face, mine gas density in the other branches has no relation to the airflow's circulation. It depends on the discharged gas volume in the work face and the supplied amount of the fresh air. The highest point of the mine gas' density in the system is still within that in the return current. (Du tailiang 1997).

1.3 *Advantages of the controllable circulatory ventilation*

1. The application of the controllable circulatory ventilation, especially using it with dust removal fan will play a very significant effect on decreasing dust and improving climate in the work face.
2. In the circulatory area, the controllable circulatory ventilation can increases the effective air flow in the work and regulate the temperature and humidity in the mine. Circulatory ventilation in the contact lane can reduce the fresh volume that main fan supplies to the circulatory area and expand the scope where main fan supply air. (Ian Lowndes & Cem Sensogut 1990).
3. Controllable circulatory ventilation can save ventilated power consumption. When we use controllable circulatory ventilation, the main ventilator's power remains unchanged, but it extra increases gas circulator's power consumption. While the conventional ventilation system gets the effective air volume it needs through the main ventilator's self-regulation. So the main ventilator's power is improved accordingly.

2 PROBLEMS IN THE VENTILATION SYSTEM

2.1 *Survey of mine*

At present LiZhuang Mine Company's actual production capacity is 400,000 tons. Its main coal seam is coal 3. The mine is a mine with low density gas. Its mine seam has the tendency to combust spontaneously. It has not had the internal-caused fire. Coal dust has the explosion hazards. It takes comprehensive dust prevention measures and has explosion-proof facilities. The mine has not had gas and coal dust explosions. Its ventilation mode is central tied for spare. Air gets into the mine from the auxiliary shaft and returns from the main shaft. Main ventilator is 4-72-11 No20B centrifugal fan with motor power for 160 KW. Ventilation negative pressure is 2000 Pa and air volume is 2500 m^3/min. Fresh airflow gets into the mine through the auxiliary shaft and is divided into two parts at the bottom of the mine: one part gets into the v dark tilt for second level heading through the east motor lane; the other part goes downhill and gets into five or seven mining district alongside the east rail. Return current gets into the main return airway alongside each mining's return airway and drainages from the main shaft to the surface.

2.2 *Problems of mine ventilation system*

1. Lack of mine airflow
   When 3512B in the fifth mining area is finished, the mine production is concentrated in seventh district, in which air volume the mine requires is 2818 m^3/min.
   Q mining required = $(Q_{3704} + Q_{3702A} + Q_{3702B\ driving} * 2 + Q_{3701driving} * 2 + Q_{D\ mining} + QD_{\ pump} + Q_{two\text{-}level} * 2 + QII_{\ excavation\ horizontal\ pump} + Q + Q_{other\ storerooms}) * 1.15 = (360 + 280 + 320 + 200 * 2 + 200 * 2 + 50 + 50 + 200 * 2 + 60 + 80 + 50) * 1.15 = 2818\ m^3$/min
   Main ventilator's actual air volume is 2600 m^3/min.
2. The length of the airflow line in the seventh mining district and the two horizontal airflow line has a large disparity. The seventh mining district has insufficient air volume. It affects the mine production. The mine's work face is concentrated in the seventh mining district. The second level is the mining level. The length of the airflow path in the seventh mining district is 6610 m while that in the second level is 1060 m. The second level does not form a production system. The seventh mining area is the main production area with two production work faces 3,704 on ramen and 3702A, and 4 excavation work faces. The air volume that the seventh mining district requires is 1860 m^3/min. According to the ventilator's capacity, the intake air volume that the seventh mining district uses is 1400 m^3/min. According to the layout of the Lizhuang mine, 3702A should be finished in June, 2010 when horizontal has formed system and the seventh mining district need reduce the air volume it requires, thus ease the tension of air volume. At present, if the seventh district cannot reduce air volume it requires, it will directly affect the mine's production.

2.3 *Necessity of the controllable circulatory ventilation*

Controllable circulatory ventilation should be best used in the boundary mining area. When the airflow line is too long, mining area is lack of air volume or it is not technically feasible and economically reasonable to replace ventilation or have large scale of shaft engineering, on the premise to ensure safety produce, using controllable circulatory ventilation is an efficient way (Niu baohu 2002). Lizhuang Mine is a mine with low density gas and the density of the mine is very low. Its mine seam has not the tendency to combust spontaneously. It is possible to use the controllable circulatory ventilation. According to the seventh mining district's actual condition, using controllable circulatory ventilation is a reasonable technological project to solve air volume's shortage in the seventh mining district. To increase effective air volume by application of controllable circulatory ventilation must increase the return current's density. Gas emission in Lizhung Mine is very small. Return current's gas density in the seventh mining area is 0.1%, and that of carbon dioxide is 0.25%. Using controllable circulatory ventilation has little effects on the increase of the gas density.

3 FIX OF THE CONTROLLED CIRCULATORY VENTILATION TECHNOLOGY IN THE SEVENTH MINING AREA, LIZHUANG MINE

3.1 *Fix of the controllable circulatory ventilation area*

Lizhuang coal mine's main production area is in the seventh district, at the same time opens up the second level. During the transitional period, according to the mining area's geology, production conditions and taking the seventh mining area being a remote place into consideration, it is fixed as the circulatory ventilation area.

The problem that the circulatory air needs to solve is the seventh mining area's ventilation during the producing period. Circulatory duct in different locations, circulatory air's zone and circulatory efficiency are also different.

According to the lane's layout in the seventh mining area, Lizhuang coal mine and through the technical and economic comparison, we decide to use the original contact lane between the seventh haulage way in the back of substation and the rail lane in the seventh mining area (the seventh mining area's intake airway). (See Figure 2). Specific circulatory parameters are seen as in table 1.

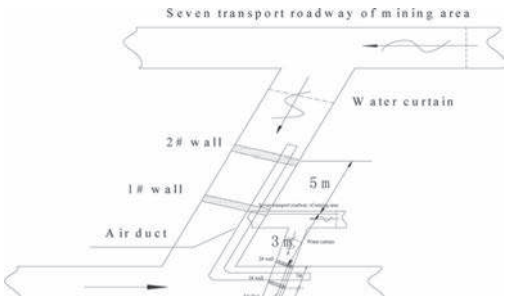

Figure 2. Program a.

3.2 *Design of controllable circulatory ventilation*

1. Selection of the project

According to safety, reliability, easiness to perform and full use of the existing lane and equipment, I design the following programs in accordance with the different layout of the circulatory duct:

Program A: Single wall type, see as figure 2. Set a confined wall in contact lane, 3~5 m away from the intake air side. Install a gas circulator in the wall and link the ventilator's exit to a silencer on which link a rubber wind tube. The wind tube should be laid along the seventh mining area's inner track road. Electromechanical device should be put outside the confined wall near the track road (where fresh air flows). Spray sprinkler should be set in the contact lane of the confined wall before the ventilator's entrance. The program is characterized by small engineering and simplicity. But the confined wall has the problem of serious air leakage. When throttle is open, it will affect the airflow's stability, thus having a less security.

Program B: Double wall type, see as Figure 3. Set the first confined wall in contact lane, 3~5 m away from the intake air side and the second 5 m away from the first confined wall. The gas circulator is installed in the second wall and the silencers are put in both the exit and the entrance of the ventilator. The silencer at the exit of the ventilator is set in the second confined wall. This silencer is linked with a rubber wind tube and connects with the iron wind tube set in the first confined wall. The layout of the iron wind tube's exit is in compliance with the wall of the seventh mining area's track lane along which the rubber wind tube's elbow makes transition. Thus it makes two water curtains for transport lane (large lane of the return current) and contact lane. The program is characterized by the fact that the confined wall has small amount of air leakage and small security. But the amount of engineering is larger than the program A.

Program C: Partition type, see as Figure 4. Set a confined wall 3 m away from the intake air side and fix the ventilator in the wall. Set another confined

Table 1. Table of circulatory parameters.

Circulatory range	Ventilator's working way	Security	Fresh air's volume (m^3/min)	Maximum of circulatory air volume (m^3/min)	Total air volume (m^3/min)	Circulation rate (%)
Mining area-7	Press	Safe	1480	500	1980	26.3

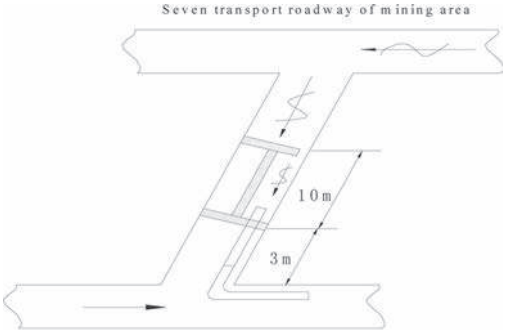

Figure 3. Program b.

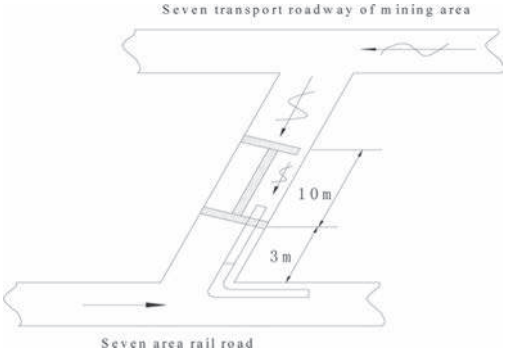

Figure 4. Program c.

wall 10 m away from the first confined wall. Separate this 10 m lane by wind wall and form a purified room by loading a ventilator and setting firefighting water curtain. The other side place electromechanical device and monitoring instrument and it also works as the personnel guards' room. Set throttle on each wind wall. The program is characterized by safety, small leakage and good cleaning effect. It also has a guards' room, but it is a large engineering and the lane need a large cross section.

By comparing the three kinds of programs, we can know program A is less secure, program C requires a large section of roadway which is a large engineering. So choose program B.

2 Engineering design of controllable circulatory ventilation

Use the contact lane between track road and the large transport lane in the seventh mining area as the cycle duct. See as Figure 3.1 Set two confined walls in the cycle duct. The first wind wall is 3 m away from the track road and a wind tube is place in the wall with a throttle. The second confined wall is 5 m away from the first confined wall in which set a silencer and throttle. The two wind walls are all set cable holes and pressure measured holes and the walls are built by stones. As it is showed in Figure 3.2, water curtain is set between the large transport lane and the contact lane in the seventh mining area. There are also CO and CH_4 probes before the entrance of the ventilator to measure the ventilating status of the circulatory current.

3 Selection and installation of the circulatory ventilator

1 Selection of the circulatory ventilator

Basis of the circulatory ventilator's selection: based on the required air volume, wind resistance and the established circulation rate in the circulatory area, and taking the match of the circulatory ventilator into consideration, we can know the wind pressure that the circulatory ventilator produce.

Parameters of the circulatory ventilator:

Air volume $Q_f = 500$ m^3/min

Wind pressure $H_f = (R_{2+} R_c + R_3) + R_4 = 1.156 \times 31.72 + 0.092 \times 8.32 = 1161.7 + 6.3 = 1168$ Pa

We can choose 3 BKJ66-11 NO4.5, two sets of which operate simultaneously, the other for standby. Its properties are:

Q_f = 170~300 m^3/min, H_f = 1000~1900 Pa, N = 8 KW, n = 2950 rpm its performance.

2 Installation of the circulatory ventilator

Circulatory ventilator is fixed on the circulatory duct's shelf. Place one circulatory ventilator on the lower deck and two on the upper deck. The interval distance is 0.2 m among the ventilators and ventilator on the lower deck is 0.3 m away from the lane's floor. There is a silencer on both the exit and entrance of the ventilators. Air regulator is set at the entrance of the ventilator. A sealed cover is placed at the entrance of the alternate ventilator

Table 2. List of each program's devices.

Program	Airtight wall	Air door	Remarks
A	One (one door)	Φ600 mm iron fan drum 3 m (the length of joint is 1 m), a number of rubber fan drum	Connect three fans (two working, one standby)
B	Two (two doors)	Φ600 mm iron fan drum/3 m (the length of joint is 1 m), a number of rubber fan drum	Connect three fans (two working, one standby)
C	Three (three doors)	Φ600 mm iron fan drum 3 m (the length of joint is 1 m), a number of rubber fan drum	Connect three fans (two working, one standby)

to prevent airflow's short circuit. To ensure that airflow is short circuit when the ventilator stops running, the following measures should be taken: wind tube in the exit falls down by its own gravity when the ventilator stops working and the current flows out from the auto-confined circulatory ventilator; fix a wooden cover on the entrance of the ventilator and seal it manually when the ventilator stops working.

4 Electrical equipment

Electrical equipment should be installed reliably to ensure circulatory ventilator works continuously and normally. Explosion-proof switch and other electrical equipment's should be installed in the fresh current outside the confined wall near the big track lane in the circular duct. It requires using "three spot, methane and carbon monoxide atresia".

5 Eliminating of the noise, dust and fire

To reduce the noise, install a FJZX-1-silencer on the two ends of the ventilator, letting the ambient noise is less than the regulation's requirement. Let the circulatory current gets through the water curtain which is placed in the seventh mining area's big transport lane and contact lane to be purified before flows into the ventilator. Thus it can eliminate the dust and fire, and reduce its heat.

6 Others

Install CO and CH_4 probes before the circulatory air duct, 5 m away from the entrance of the ventilator to achieve unrestricted power failure alert and make sure the circulatory ventilator's wind, electricity, CO and methane closed. At the same time special attention should be paid to eliminate the fires caused by external reasons in the circulatory area by using reliable measures.

3.3 *Safety and technical measures of the controllable circulatory ventilation*

To ensure the security of the controllable circulatory ventilator, the following safety measures must be strictly observed:

1. Ensure circulatory ventilator works continuously and normally and power should be safely supplied 24 hours. On special circumstances, it can have power cut when it is approved by the mine's chief engineer and measures has taken. (S.Tate 1994).
2. When the circulatory ventilator stops supplying air, original ventilation system must return to work to prevent current in the circulatory duct from short circuit. When the ventilator stops, personnel on the duty in the mine must report this to the mine's dispatcher and organize personnel to deal with immediately. When restart the circulatory ventilator, power must be restored manually.
3. Sealed devices should be installed at the wind tube's entrance of the circulatory ventilator. Once the ventilator stops working, block the circulatory wind's duct immediately.
4. In the circulatory area, thorough measures must be taken in case of fire, so flame retardant duct must be used.
5. Install CH_4, CO probes at the entrance and the exit of the circulatory duct. When the gas density rises to the limited level, it should ensure the power failure and alarm, and restores the original ventilation system.
6. Purify the airflow by the water curtain before the circulatory air enters into the ventilator, letting the dust in the mixed air is not more than the regulation's standard.
7. A silencer is set at both the entrance and the exit of the circulatory ventilator, letting the noise around the circulatory ventilator is less than the regulation's requirement.
8. Establish specialized responsibility and make clear divisions for each people's responsibility. Implement concerning administration. Ask expert people to manage circulatory ventilation system and send specialized people to the underground on duty in each class.
9. Strengthen safety supervision for the ventilation in the circulatory area, establish parameter recording account for CH_4, CO, air volume, dust and circulatory air system, and write circulatory fan's running. (Weimin Hu et al. 1998)

10. Install U water meters on the two sealed walls in the circulatory air duct to check changes of pressure. If the system's pressure is abnormal, the entire circulatory system must be checked immediately.
11. When there are serious disasters (CH_4, fire, flood, dust, and so on) in the circulatory area, circulatory ventilator must be stopped immediately and normal ventilation system should be restored. The disasters should be handled according to the disaster prevention and treatment plans.

4 CONCLUSION

According to the theoretical analysis of the controllable circulatory ventilation system as well as the system's practical application in Lizhuang coal mine, we get the following conclusions:

1. The use of controllable circulatory ventilation can improve the mining face's effective air volume in the mining area, and improve work face's climate condition to achieve ventilation and energy saving.
2. The use of controllable circulatory ventilation can meet the seventh mining area's required air volume 1860 m^3/min. The visible natural wind volume is 1400 m^3/min. When the controllable circulatory ventilation is used, the air volume it supplies to mining area is 500 m^3/min. Compared with the improved air volume that the main ventilator supplies and the auxiliary ventilator, mine's total in and out air is small and we have less energy consumption. Rate of the mine's effective air volume is improved.
3. To ensure the safety of controllable circulatory ventilation, safety technical measures must be strictly observed.

Research on terminal mining support technology of the hard stratified roof in the fully mechanized coal face

Li Chen, Guo Qiang Hao, Ping Liu & Shi Chao Peng
Hebei University of Engineering, Handan, Hebei, China

ABSTRACT: Combined the condition of the roof with the terminal mining process under fully mechanized coal mining face, caving and the stress of the roof is analyzed. And based on the analysis a strong stratified roof support scheme was put forward in Rongtai mine, which worked successfully in the field. This technical experience not only creates a good convenience for the Fast Moving, shortens the time slope expansion to dismantling equipments at the terminal mining process, but also achieves a reduction in cost and increases efficiency at the same time. In addition, it has a strong promotional value.

1 INTRODUCTION

The retracement of fully mechanized working face is an important process of mining, which affects the speed of Face Moving, Mine Safety and Efficiency directly (Li & Liu 2010, Zhao 2005, Zhao 2009, Wang & Zhang 2009, Zhang & Zhang 2009). So, the key of high production and high efficiency in coal mines is Fast Moving, and how to choose a reasonable support method to maintain the stability of back channel becomes the key technology of Fast Moving (Yang & Lian 2006, Liu 2004, Li 2006).

When Full-mechanized working face is stopped, the surrounding rocks get closer to the working face, thus, the rib spalling gets more and more serious, however, recycling supports requires a large secure space, in order to recycle supports safely, the support method which commonly used at the terminal mining of fully mechanized coal face is combined support that the combination of network, rope and anchor net, and it creates a secure condition for recycling supports.

In order to improve the existing support form at the terminal mining of fully mechanized working face, We put forward a reformational and experimental scheme that no networks and ropes are used when supporting the roof of 10104 working face according to the data of roof dynamic observation and the manage experience of working face in two full-mechanized working faces called 10102 and 10104 of Rongtai coal mine.. And this scheme can meet the requirement which evacuate supports safely and efficiently and the roof management requirement, shorten the time which prepare the mining expansion and the cycle time of moving, then more time can be used for goaf protection, so its technical and economic benefit is obvious.

2 GETTING STARTED

The 10104 face is the first nearly flat and fully mechanized mining face in Rong tai coal mine, and it has been finished mining. Its face length is 180 m, face advance length is 863 m, and coal-seam thickness is steady, the average thickness is 2.79 m, the angle is about 1~8°.The geologic structure in this face is simple, the attitude of coal is gently, no fault, no magmatic, no collapse column exists in this face, but there are rolling folds in the floor; the roof consists of the thickness of the roof for 9 m, pale, dense and uniform limestone with horizontal bedding; the floor consists of thickness of 3.5 m, light gray, tidal flat depositional environment of mixed flat and marsh sedimentary mudstone. The columnar section is shown in figure.1.

3 THE PARAMETERS OF SUPPORTING

According to the analysis of "three parts on the transverse" and "three parts on the vertical" and the 9 meters' roof which consists of layered limestone. We use the support method in the mining face, it ensures the secure withdraw of the equipments in the fully mechanized mining face, combined with the conditions of the roof and floor.

3.1 *Operation without online and onrope*

At the terminal mining process, the first row of bolts are started constructing away from stopping line 9 meters, the bolts are made of steel with thread, the model is φ22 mm × 2000 mm, the distance between two bolts is 1500 on the vertical,1800 on the transverse. All the bolts are equipped with

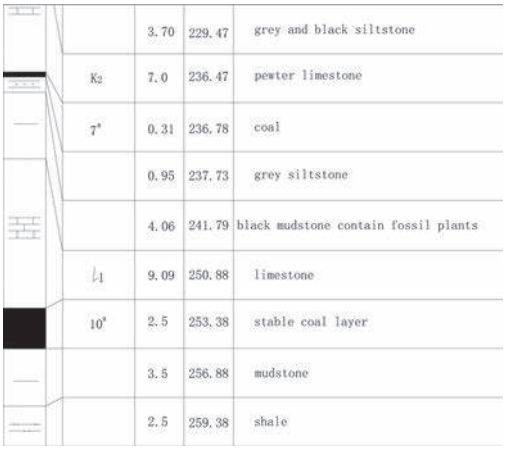

Figure 1. The columnar section of rock in 10104 mining face.

anchor agent to ensure the supports can be not buried by the gangues which come from the carving zone when the hydraulic supports are retreated. The supporting scheme is shown in figure 2.

3.2 *Support design of back channel*

When listing facts use either the style tag List signs or the style tag List numbers.

3.2.1 *Construction technology*

The back channels are started broadening as the mining face is 3 meters' distance to the stopping line, stop moving the supports, meanwhile, separate all of the advancing jacks of the supports and the scraper conveyor, use hydraulic props to accomplish the operation that moving the scraper conveyor, erect a hydraulic prop between the scraper conveyor and the supports every 3~5 supports, adopt the way that the emulsion is offered in a distance to move the scraper conveyor, clear the float coal in front of the supports and beside the supports before moving the supports, people are forbidden stranded at the mining face channel when scraper conveyor is moved by hydraulic props.

3.2.2 *Support parameters design*

Back channels' height is 3 meters; its width is also 3 meters. Adopting the bolts which made of steel with thread and the model is φ22 mm × 2000 mm to support the roof. The distance between two bolts is 1500 on the vertical, 1100 on the transverse, and they are equipped with mesh reinforcements and ladder beams; there is a row of strand anchor cable in the roof, the model of the strand anchor cable is φ17.5 mm × 6000 mm, the distance between two

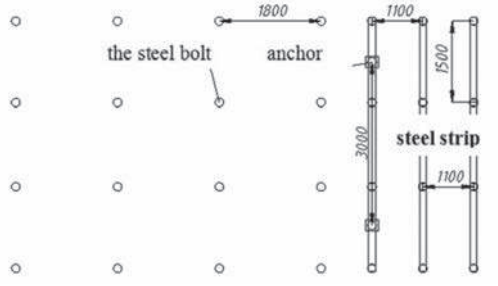

Figure 2. The supporting scheme.

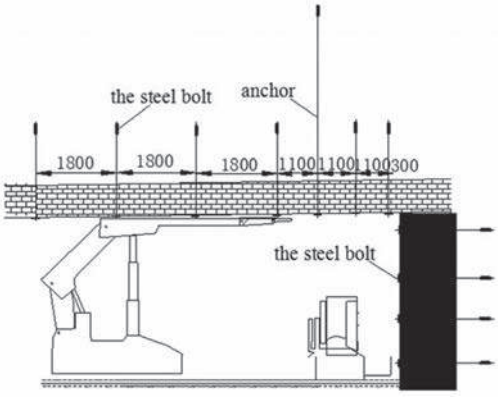

Figure 3. The construction design.

adjacent strand anchor cable is 3 meters, and every strand anchor cable is equipped with the metal pallet which the model is 300 mm × 300 mm × 16 mm and 3 cartriges (one is high-speed, anther two are medium-speed). Laying plastic mesh which the model is 3000 mm × 1200 mm on the coal wall and making it connect to the anchor net; the model of the bolt is φ18 mm × 1600 mm, the distance between two adjacent rows is 800 mm × 1000 mm, and every bolt is equipped with an anchor agent. The construction design is shown in figure 3.

4 TECHNICAL AND ECONOMIC BENEFIT ANALYSIS

4.1 *Technical efficiency analysis*

We can ensure the stability of the roof and the safety and the portability of the back channel with the combined support of bolts, anchor cables and supports.

Adopting double shield to control the trigonal area effectively. Hydraulic props were used to expand the trigonal area once upon a time, but,

they could affect the adjusted direction of supports when the supports were cycled, and, hydraulic props should be erected, then cycled frequently, it make workers be of high labor intensity and high risk. By using the double shield can shorten the workers' labor intensity, provide the work efficiency and raise the safety.

There are no support nets between roof and top beam of the supports, so, it can not cause the auxiliary work which are caused by broken the top wire in the withdrawal period, and the roof behind the shield supports can collapse fully as the shield supports are moved forward, and it would not appear the flap top phenomenon in a large area.

Adopting the channel which transport the supports, by this way the workers can avoid the auxiliary work caused by the wipe angle, the bracket line, the corners and the derailment of loaded car for transportation.

According to the analysis of the data about roof bedding separation in the condition without online and onrope, it shows the roof is stable, and roof bedding separation is not obvious.

4.2 *Economic benefit analysis*

By the reform of supporting way of last roof of hard roof, the duration Shorten seven days in the tunnel expansion and labor cost has been saved by ¥127,000, the cost of materials is reduced by more than ¥106,000.The reform achieves cost efficiency, minimize labor intensity of workers, and improve the speed of face removing in overall and save time. This way effectively avoid the Problem of coal wall spalling or ground up and other secondary issues, which are caused by a long time of the working surface ending mining or dead time of the face mining equipment. This process is the accumulation of advanced experience quick moving of fully mechanized coal face and has more important practical significance.

5 CONCLUSIONS

Through the analysis of the supporting effect and the concrete construction technique, the adoption of the supporting method can effectively control the shelves space roof surrounding rock. Meanwhile, it can make the surrounding rock steady, and fully meet the requirements of the use of the roadway, so that it can achieve the expected effect of support. The construction is simple and convenient, and it is easy to operate, and we can get good economic benefit. It is feasible in technology and theory, and provides new experience and methods for the strong stratified roof at the end of the fully mechanized coal face mining support.

Comparative experimental study on dynamic mechanical properties of anthracite and limestone

Yong-Chun Miao
School of Resources and Safety Engineering, China University of Mining and Technology (Beijing), Beijing, China

Yu-Kai Fu
Coal Mining and Designing Department, Tiandi Science and Technology Co., Ltd., Chaoyang District, Beijing, China

ABSTRACT: In order to understand the failure mechanism of rock under dynamic loading, such as explosion, impact and earthquake, the different impact speed experiments of anthracite and limestone sample were conducted by using Φ50 mm Split Hopkinson Pressure Bar (SHPB) experiment system. The experimental results showed that the dynamic mechanical properties of Anthracite and limestone are obviously different. The dynamic stress-strain of anthracite is generally has leaping features. Obvious nonlinearity is presented in the initial rising stage and the degree of nonlinearity is inversely proportional to the impact velocity. However, dynamic stress-strain curve of limestone is a straight line in the initial stage, the deviation of linear slope is small. The stage has linear-elastic properties; Anthracite and limestone both have the tendency of increasing impact rate while the plastic deformation and the ultimate strength increased. Whereas the plastic deformation of limestone is smaller than the plastic deformation of anthracite. According to the dynamic stress-strain curve, the dissipated energy of anthracite and limestone and the dissipated energy of anthracite and limestone both has the weak power function increasing trend with the increasing of the impact rate based on calculation.

1 INTRODUCTION

With the rapid development of the national economy and the increased mining depth coal and rock dynamic disaster is increasing ay by day. In order to ensure life safety, safe, reasonable and efficient mining method are very necessary. Then the research on dynamic mechanical properties of underground rock is also very important[1]. Almost all of the dynamic disaster, such as broken rock, rock burst, coal and gas outburst and other dynamic disasters had certain correlation with the rock failure under impact load and stress wave's propagation in the rock[2]. Because research on the dynamic mechanical properties of rock is minimal in our country, many law needs to refer to foreign data[3,4], which leads to the lack of theoretical basis in China. Rock burst and other dynamic disaster tend to occur in coal seam with limestone roof. Therefore, in order to effectively control the mine dynamic disasters, we must reveal its dynamic mechanical properties, thus it is very important to do the comparative study on dynamic mechanical properties of coal and limestone.

The research on the dynamic mechanical properties of rock is earlier in Europe and United States[5]. Hydraulic pressurizing or drop hammer test method was used in early stage. The hydraulic pressure method by B. Bresler[6] could achieve the strain rate of 1 s^{-1}. And the drop hammer test method used by B. P. Hughes[7,8] could reach to 10 s^{-1}. Because of the inertia of the drop hammer, it was hard to ensure that experimental results measured by drop hammer test method were the real dynamic properties of material. SHPB method was used to test the dynamic mechanical properties of concrete by L.E. Malvern[9]. This method reduced the influence of inertia effect and the loading strain rate could reach 103s^{-1}. Through this method we have a new understanding with strain rate sensitivity of concrete material. In 1984, the mechanical characteristics of coal under quasi static load and impact load were studied by Klepaczko from Canadian Manny Ba University[10], whose research results showed that coal modulus was not sensitive to the strain rates in a certain range of strain rates, but when strain rates exceeded the critical value, the elastic modulus and the crack propagation would have an obvious different law and increased in linearity with the increase of strain rate.

Wu and Gao[11] had studied on the mechanical properties of Yangquan coal under the

10^{-1}~104 MPa/s loading rate with the fast loading machine, the results of the research showed that coal tensile, compressive strength and elastic modulus have increased as the loading rate increased. Shan[12] of domestic scholar studied anthracite in Yunjialing coal mine with SHPB experiments, and believed that dynamic stress-strain curve showed the nonlinearity in the initial stage and the degree of nonlinearity is inversely proportional to the impact velocity. Many scholars had only studied qualitatively the dynamic mechanical properties on coal and rock, but had not studied the difference of dynamic properties of two kinds of rocks. This paper aims to study the difference of dynamic properties of coal and limestone and to carry out quantitative analysis on the dissipated energy through impact experiment of coal and limestone under different speeds.

Dynamic mechanical experiments were completed with SHPB test device from China University of Mining and Technology (Beijing), The Split Hopkinson Pressure Bar (SHPB) is currently widely used to study dynamic strain rate. Using φ50 mm SHPB test device, dynamic mechanical properties of coal and limestone under different strain rates were analyzed and mechanical properties of coal and limestone were explained from the structure.

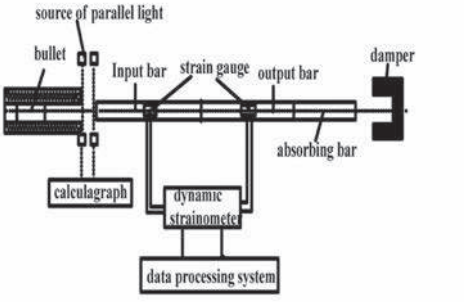

Figure 1. SHPB experimental system.

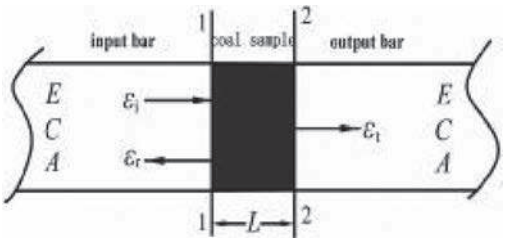

Figure 2. Principles of SHPB experiment.

Figure 3. Physical map of the SHPB test system.

2 SHPB EXPERIMENTAL SYSTEM

2.1 *Sample preparation*

Coal and limestone samples are both cylinder-shaped, and have size of Φ50 mm × 50 mm. Parallel degree was controlled within the range of 0.02 mm error in the sample processing to guarantee the surface cleanliness. In order to reduce the friction effect between the pressure bar and the specimen, ensure good contact and meet the SHPB uniformity assumption, graphite lubricant is evenly smeared on the two ends of specimens.

2.2 *SHPB experimental system and device*

Dynamic mechanical experiments was completed with SHPB test device from China University of Mining and Technology (Beijing), The SHPB device consists of an impact rod (bullet), input and output bar, the test samples are sandwiched between the input and output bar. The typical SHPB experiment system, principle and object diagram are respectively shown in Fig. 1, 2, 3.

The bullet has the diameter of 50 mm and the length of 400 mm. The input and output bar are both 50 mm in diameter, 2000 mm in length, made of steel and 200 GPa in elastic modulus. Semiconductor strain gauge was symmetrically attached to the central location of input and output bar.

The basic principle of SHPB experiment is the stress wave propagation theory in elastic slender bar, which is based on two basic assumptions that one is one-dimensional assumption (also known as plane assumption) and other is uniform stress assumption. The one-dimensional assumption considered that each cross section in elastic bars always keeps the plane state in the propagation process of the stress wave in the slender bar. Uniform stress assumption assumed that the stress

wave propagation repeated 3~4 back and forth in the specimen and the stress was equal everywhere. The simplified calculation formula is as follows:

$$\dot{\varepsilon}(t) = -\frac{2C_0}{L}\varepsilon_r(t) \tag{1}$$

$$\varepsilon(t) = -\frac{2C_0}{L}\int_0^t \varepsilon_r(t)dt \tag{2}$$

$$\sigma(t) = \frac{A_0 E_0}{A}\varepsilon_t(t) \tag{3}$$

In the formulas, $\dot{\varepsilon}(t)$, ε(t), $\sigma(t)$ is respectively strain rate, strain and stress. C_0 is the elastic wave velocity in pressure bar, 5060 m/s. E_0 is the elastic modulus of bar material, 200 Gpa. A_0, L is respectively cross-sectional area and length of specimen, The impact velocity of experiment was controlled within 2~6 m/s. Because the impact velocity of bullet is provided by high pressure gas, the impact speed of coal and limestone samples will vary slightly.

3 DYNAMIC MECHANICAL ANALYSIS

3.1 *Waveform curve analysis of anthracite coal and limestone*

The striking bars (bullets) acquired a certain speed from gas power, then did central collision with the input bar, a pressure pulse εi was generated by input bar and propagated along the axial of bar, the pressure pulse spread to the specimen, since the wave impedance of input bar and specimen was different, stress wave will generate multiple reflection on both ends of the specimen surface and lead to uniform deformation of specimen. Part of the input stress wave propagated output bar through the specimen (the transmitted wave εt), the transmitted wave was captured by the absorbing bar, finally was absorbed by the damper, another part became the reflected wave εr, and returned the input bar, the signal was collected by the strain gauge arranged in input and output bar.

In the Φ50 mm SHPB system, the incident bar impacts anthracite coal and limestone specimens under the different impact velocity, strain curve obtained in the input and output bar is shown in Fig.4 and Fig.5.

The figure 5 shows that incident wave and reflected wave of anthracite has a good agreement. Meanwhile, the corresponding transmission wave descend immediately at maximum stress and wave shape performs linear attenuation. The speed of attenuation (the slope of line) is related to the loading intensity and the degree of fragmentation of samples. This phenomenon indicates that the

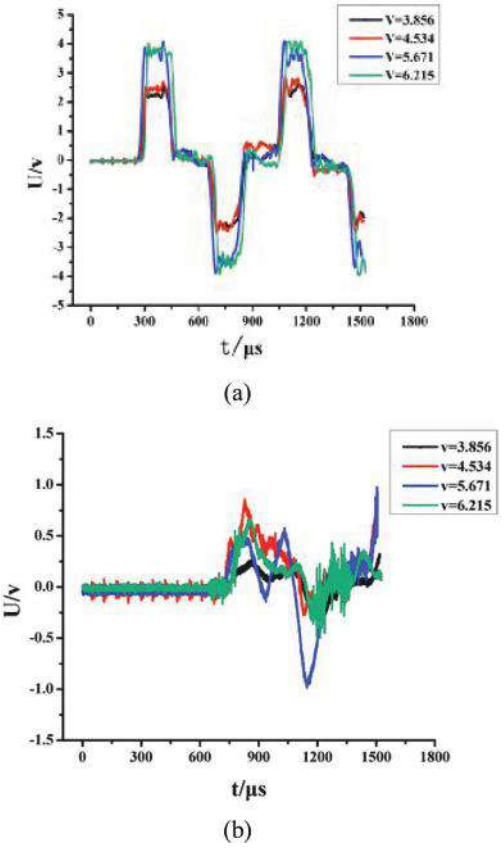

Figure 4. (a) incident wave and reflected wave of anthracite; (b) transmission wave of anthracite.

anthracite specimen has badly damaged and generate cracks, the wave will be reflected at the crack free surface.

The reflection wave form of limestone is "W" shape and the second wave trough is shallow. this indicates that the limestone specimens has not badly damaged, Moreover, the transmitted wave does not descend immediately at maximum stress, but lasts a period of time, which shows that limestone specimens did not serious damage like the anthracite. From the waveform curve anthracite coal and limestone, there are significant differences between the two materials in terms of dynamic mechanical properties.

3.2 *Dynamic stress-strain curve of anthracite coal and limestone*

Elastic modulus (E) of steel pressure bar in experiment is equal to 206000 MPa. Wave velocity C_0 is equal to 5060 m/s, cross-sectional area A is equal to 625 πmm^2, the specimen thickness L = 50 mm.

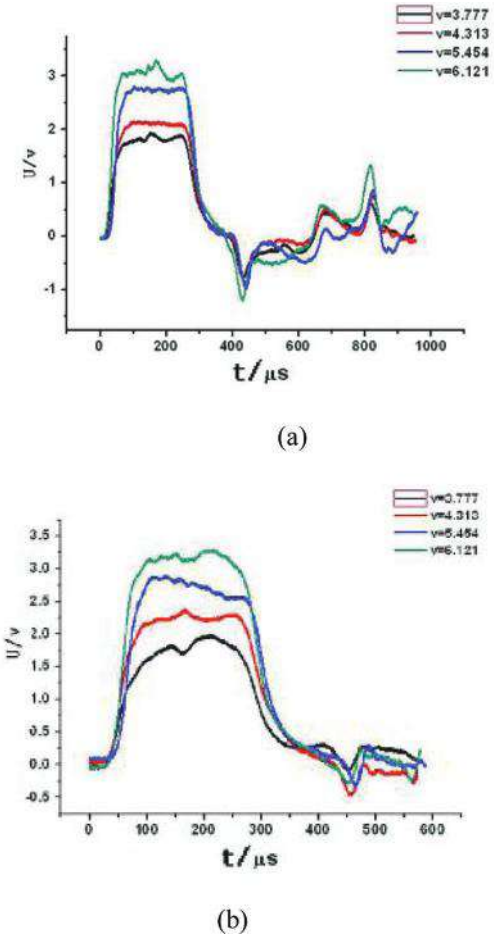

Figure 5. (a) incident wave and reflected wave of limestone; (b) transmission wave of limestone.

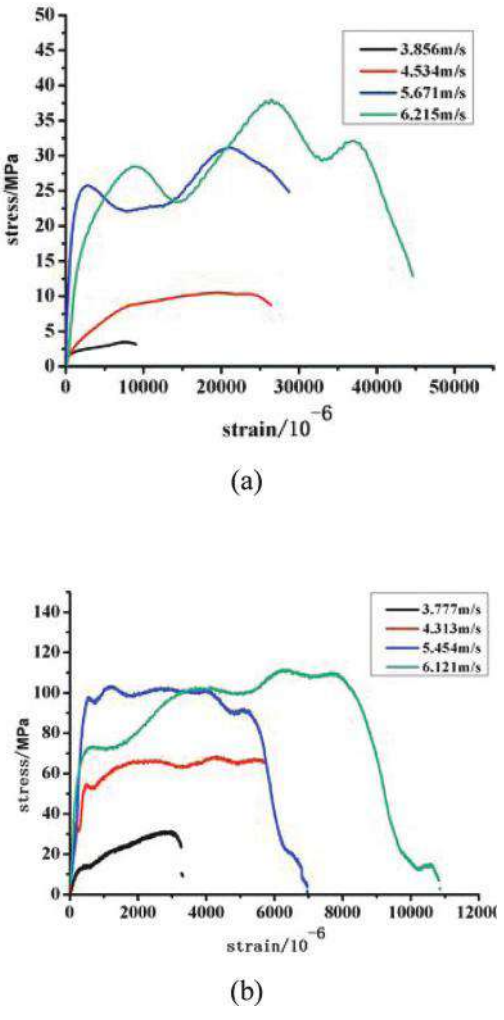

Figure 6. (a) Dynamic stress strain curve of anthracite; (b) Dynamic stress strain curve of limestone.

The dynamic stress-strain curve of specimen was obtained through (1), (2), (3) formula. The stress-strain curve of specimen is shown in Fig.6.

As shown in Fig.6, dynamic stress strain curve of anthracite was markedly different from limestone. The stress and strain of anthracite in general are characteristic of leap before the maximum value. After rising to the first maximum, stress decreases firstly and then increases to a maximum value with increasing strain. In the initial stage, dynamic stress strain curve of anthracite shows obvious nonlinearity, which is more obviously with the decrease of the rate. The slope of curve is also increasing with the increase of impact velocity in the initial stage, but different is relatively large. The faster impact rate increases, The greater the plastic deformation of anthracite coal is. However, the dynamic stress strain curve of limestone is basically a straight line at the initial stage. Deviation is smaller with different rate, the segment can be very good overlap. It is believed that rock in this stage is linear elastic. From the Fig.6, we can also see that strain of limestone is significantly less than anthracite. The curve have the same properties that the faster impact rate increases, The greater the plastic deformation of limestone is.

Compared with limestone, the anthracite has bigger porosity, more endogenous fracture and stronger plastic deformation. Whereas, limestone has more strength, brittleness and homogeneity. Therefore, part of crack propagates and part of crack closes due to endogenous fracture in the impact process of anthracite coal, and the properties of strain hardening will appear. Moreover, this

properties is more sensitive to high strain rate, but not sensitive to low strain rate. while in the impact process of anthracite coal, the strain hardening properties is not obvious and more insensitive to high strain rate due to Limestone's uniformity, good compactness, and little cracks.

3.3 *Coal and rock dynamic comparative analysis of the impact of failure modes*

As can be seen from experimental results, anthracite sample at 75–125s-1 strain rate, cylindrical sample were destroyed by the impact occurred. When the strain rate is low (75–82s-1), there is a higher degree of fragmentation close to the incident lever, and near the side of the transmission lever broken a lesser extent, it shows that the stress wave in the process through the specimen, in the incident lever side of the crack growth due Anthracite coal sample, absorbing part of the stress wave energy, causing the stress wave attenuation occurs, so that the end of the specimen can not be broken for the specimen to provide enough energy; As the strain rate increases, the pieces of specimen damage scale was significantly decreased, while the number of fragments increased significantly, showing that a strong correlation between strain rate, and anthracite coal sample crushed particles are relatively uniform, but particle dispersion is not.

Sandstone specimen strain rate of 75s-1 there was a certain crack, but not destroyed. In the 82–125s-1 strain rate range, the effect of cylindrical specimens under attack and damage, and equally close to the incident lever side of the lever features a high degree of fragmentation. The fragmentation character of sandstone samples and anthracite coal is markedly different, sandstone sample crushing particle morphology varies widely, the discrete particles is large, especially in the effect of 125s-1 strain rate, the local sample crushed into powder, partial sample also retains good integrity, this is mainly due to the large number of irregular sandstones cracks, bubbles and other defects result in the strike, the local stress concentration of the first failure occurs, resulting in crushed particles discrete greater.

3.4 *Breaking dissipation energy analysis of anthracite coal and limestone*

When rock was subjected to dynamic loads, the nonlinear deformation was also significantly increased with the impact velocity (strain rate) increased. The breaking dissipation energy also could be used to measure the difficult degree of rock breaking in addition to breaking strength and elastic modulus[13].

The dissipation energy of sample E_s is:

$$E_s = E_I - E_T - E_R \tag{4}$$

The incident energy E_I, reflex energy E_R, transmission energy E_T is respectively:

$$E_I = \frac{A_0}{\rho C_0}\int_0^T \sigma_I^2(t)dt \tag{5}$$

$$E_T = \frac{A_0}{\rho C_0}\int_0^T \sigma_T^2(t)dt \tag{6}$$

$$E_R = \frac{A_0}{\rho C_0}\int_0^T \sigma_R^2(t)dt \tag{7}$$

In the formulas, $\sigma_I(t)$, $\sigma_T(t)$, $\sigma_R(t)$ is respectively the incidence, reflection and transmission stress at some point. Compressive stress is positive for the incident and transmitted stress. However, tensile

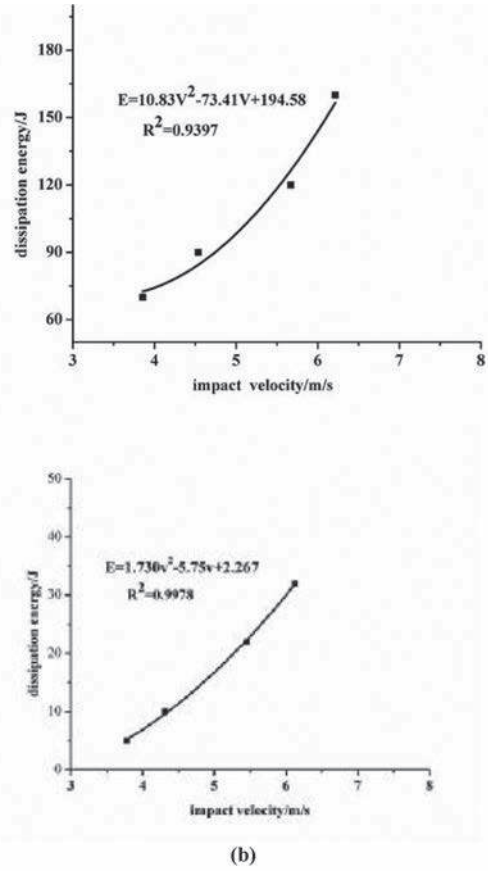

Figure 7. (a) Energy dissipation curve of anthracite coal; (b) Energy dissipation curve of limestone.

stress is positive for reflecting stress. ρ, C_0 respectively represents press bar density and stress wave velocity of elastic bar. T represents the continued time of stress wave. A_0 represents the cross sectional area of elastic bar.

According to the dissipated energy formula that was used in the SHPB dynamic impact rock specimen, incident energy, reflex energy and transmission energy could be calculated under different impact rate. Finally the change tendency of dissipation energy with the impact velocity was shown in Fig. 7.

As seen from the Fig.8, the dissipative energy of anthracite coal and limestone has a increasing tendency that shows a weak power function relationship or linear relation, and the growth rate of energy dissipation is faster with the increase of impact speed. In other words, the dissipation energy and the degree of fragmentation of anthracite is larger, higher than that of limestone in the same impact rate.

4 CONCLUSIONS

The impact experiments of anthracite and limestone samples were conducted by using Φ50 mm split Hopkinson pressure bar (SHPB) experiment system, the dynamic mechanical properties of samples are analyzed under impact loading. Finally, the relationship between the dissipation energy and impact velocity is studied. The main conclusions are as follows.

Dynamic stress strain curve of anthracite was markedly different from limestone, in general are characteristic of leap. In the initial stage, dynamic stress strain curve of anthracite shows obvious nonlinearity, which is more obviously with the decrease of the rate. However, the dynamic stress strain curve of limestone is basically a straight line at the initial stage, deviation is smaller with different rate and the segment can be very good overlap. It is believed that rock in this stage is linear elastic. Anthracite and limestone have both the tendency of the plastic deformation and the ultimate strength increases with the increase of the impact rate, but the plastic deformation of limestone is smaller than the plastic deformation of anthracite.

With the increasing of impact speed, the dissipative energy of anthracite coal and limestone has a weak power function increasing tendency and the growth rate of energy dissipation is faster for anthracite. That is to say anthracite could absorb more energy and show more broken than limestone in the same impact rate.

Safety Engineering College of North China Institute of Science and Technology, Beijing, China

Genyin Cheng & You Cheng
Science and Technology Division of North China Institute of Science and Technology, Beijing, China

ABSTRACT: Along with deep mining of coal mine, in the condition of higher stress and gas pressure, the burst triggering mechanism will change. Firstly, according to the distribution of the stress and gas pressure in the front of working face, and there are some broken coals in the top of burst coal seam, and combining with characteristic, the physical mechanical model of burst coal was constructed in the condition of higher stress and gas pressure; then, the mechanical mechanism of burst coal was analyzed, and the theoretical formula of burst energy was deduced. The results show the relative motion is rolling friction between burst coal and roof in the condition of higher stress and gas pressure, and the relative motion is sliding friction between burst coal and floor in the other conditions, the burst energy increase with the depth of burst spot by exponential law. Therefore, in the condition of higher stress and gas pressure, the elastic deformation energy of coal (rock) and the expansion energy of gas release instantly, On the one hand, the burst energy increases, On the other hand, the resistance falls. Therefore, the action mechanism which prevents and controls the burst by enhancing the distressed zone width is improving the energy consumption of burst happening.

1 PREFACE

With the increment of mining depth, there are a series of new phenomena on deep rock mechanical behavior, and the most prominent is the "three high and one disturbance" complex mechanical environment (i.e. "three high" refer to high ground stress, high temperature and high gas pressure are, and "one disturbance" refers to the excavation disturbance strongly) (HU Qian-ting, et al. 2007, Liu Weidong, & Zhang Rongyu. 2006, Pan Liyou, et al. 2006). In the depth environment, coal (rock) and gas dynamical disasters (such as rock burst) which are related closely to stress and mining disturbance is also increasing in coal mining engineering, and showing a new and more complicated disaster characteristics. In order to effectively prevent the occurrence of burst, scholars at home and abroad have carry out a series of fruitful work, bring forward the burst generating mechanism (such as strength theory, energy theory, stiffness theory, impact orientation theory and instability theory), and the rock burst prediction index (such as elastic deformation energy index, impact energy index and dynamic failure time). The above-mentioned achievements have been widely used in coal mine (F. Otuonye, & J. Sheng. 1994, Germanovich L N, et al. 1993, K. Sato, & Y. Fujii. 1989, Lama R D, & Bodziony J. 1998, Li S, & Zhang H W. 2002, QI Li-ming, et al. 2007, Qi Qingxin, & Dou Linming. 2008). Although the great achievements of burst stress have been made at home and abroad, the research which the coupling action of higher stress and gas pressure lead to the disasters in deep mining is still less. Theoretical researches have been carried out on the burst stress trigger mechanism in this condition, and it may provide theoretical guidance to the prevention and cure of coal (rock) dynamical disaster in deep mining.

2 THE COAL MECHANICAL MODEL UNDER THE COUPLING ACTION OF HIGHER STRESS AND GAS PRESSURE

In the front of working face, firstly, the stress increases, secondly, decreases, finally, tends to be stable. Gas pressure increases gradually, and eventually tends to be stable. For the coal seam prone to burst, there is a thin layer of smash coals (about 0.1 m to 0.2 m) between the coal seam and roof (Huang RQ, & Wang XN. 1999, Jin Liping, &

Xian Xuefu. 1993, QI Li-ming, et al. 2007, Xie Heping, & Pariseau W C. 1993, Zhang Wanbin, et al. 1992, ZOU yin-hui, et al. 2007). The coal would be fractured in the front of working face in the condition of stress-concentrated, turn from elastic state to plastic state, and at the same time, a large number of high-pressure gases were desorbed. The air flows into the top of the coal seam along the seam cracks, and the soft broken coal between coal seam and roof was ejected out under the action of high-pressure gas flow, leaving a little of rigid coal particles between coal seam and roof, and it is shown as figure 1.

In the front of working face, when the coal turns from elastic state to plastic state, the elastic deformation energy would release. The amount of energy directly depends on burst energy index, the release speed depends on the dynamic failure time, and the amount of releasing energy depends on the relative size of these two indicators in unit time (Li Zhonghua, & Pan Yishan. 2002, Lin Baiquan, & Cui Hengxin.1998, Litwiniszyn J.1990, Paterson L. 1986, S. Murakami. 1983). The greater of releasing energy is in unit time, the higher of additional stress. Coal does not belong to the rigid body; therefore, the energy will be spread to the mining face by the form of stress wave.

In the process of stress wave spreading to the working face, coal body along the way will absorb some of the energy and distort under the disturbance of stress wave. Because of deformation and instability of coal in the front of mining face, the consumed energy is different in the different condition of stress and gas pressure. A unit coal close to mining face wall maybe occur bending deformation and even instability collapse under the affect of stress wave, and the burst takes place in the macro.

Under the effect of stress wave, the mechanical model of each unit coal can be simplified as follows: stressed at both left and right sides, the bottom is fixed, and has some shear strength, and the upper end contacts with roof through a spherical

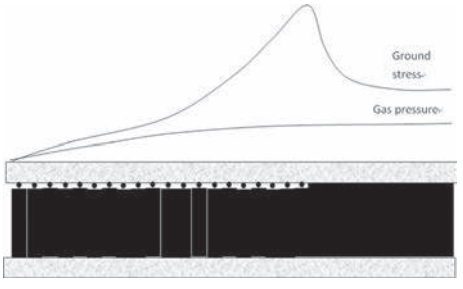

Figure 1. The structure diagram of coal and rock before burst happening.

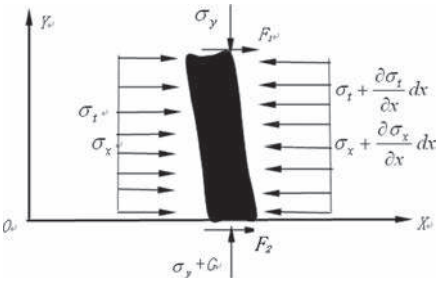

Figure 2. The stress diagram of burst coal body.

coal, and the relative motion between it and spherical coal belongs to rolling friction.

When the elastic deformation energy and the gas expansion energy released by coal burst is higher and the additional stress reaches a certain level enough to overcome the rolling frictional resistance at the top and the sliding frictional resistance at the bottom of coal seam, on the one hand, the coal was stressed and compressed further, on the other hand, the displacement towards to the low stress area (roadway coal wall) takes place, and it is shown as figure 2.

The coal in condition of forced state can be simply regarded as the cantilever beam, and both left side and right side are forced, and at the same time, the free end is also forced by the focusing load, and the whole coal (including the bottom of coal) will make a displacement.

3 THE STRESS ANALYSIS OF COAL BODY UNDER THE COUPLING ACTION OF HIGHER STRESS AND GAS PRESSURE

σ_y is the force which can act on coal seam and be perpendicular to direction of burst and MPA. according to the basic knowledge of rock mechanics, in the region of high-point stress, the stress increases exponentially basically. Therefore, it can be expressed by formula 1

$$\sigma_y = \sigma_{b_1} e^{b_1 x} \tag{1}$$

In formula 1, σ_{b_1} is the compress stress at roadway coal wall, MPA; b_1 is the coefficient describing the rate of stress change, m^{-1}; x is the depth from coal wall, m.

To the coal under the action of high stress and gas pressure, rolling friction at top and sliding friction at bottom, rolling friction and sliding friction per unit area can be expressed by formula 2–3.

$$\mu_g \sigma_y = \mu_g \sigma_{b_1} e^{b_1 x} \tag{2}$$

$$\mu_h \sigma_y = \mu_h \sigma_{b_1} e^{b_1 x} \tag{3}$$

In formula 2–3, μ_g is the rolling friction coefficient; μ_h is the sliding friction coefficient.

The additional stress generated by the release of elastic deformation energy and gas expansion energy can be expressed by formula 4.

$$\sigma_t = \sigma_{b_2} e^{b_2 x} \tag{4}$$

In formula 4, σ_t is the additional stress generated by the release of elastic deformation energy and gas expansion energy, MPA; σ_{b2} is the residual stress when elastic wave transmitted to the roadway coal wall, MPA; b_2 is the coefficient describing the rate of stress change, m^{-1}.

The coal is compressed by the action of additional stress, and the stress both left side and right side will change and achieve stress equilibrium within a short time. Then, at left side, the stress can be expressed by formula 5.

$$\sigma_x = K \sigma_{b_1} e^{b_1 x} \tag{5}$$

In formula 5, σ_x is the stress at left side, MPA; K is the coefficient of side stress.

The balance equation was built by making use of force analysis, as shown in formula 6.

$$\begin{aligned}&(\sigma_x + \sigma_t) Lm + \mu_g \sigma_y L dx + \mu_h \sigma_y L dx + \rho m L a dx \\ &= \left(\sigma_x + \frac{\partial \sigma_x}{\partial x} dx + \sigma_t + \frac{\partial \sigma_t}{\partial x} dx \right) Lm\end{aligned} \tag{6}$$

Where L = the depth of coal where burst takes place, m; m = the thickness of coal seam, m; ρ = the density of coal, kg/m^3; a = the acceleration of coal element which is analyzed, m/s^2.

The formula 6 can be simplified, as shown in formula 7.

$$\left(\frac{\partial \sigma_x}{\partial x} + \frac{\partial \sigma_t}{\partial x} \right) m - \mu_g \sigma_y - \mu_h \sigma_y = \rho m a \tag{7}$$

Putting formula 1, 4 and 5 into formula 7, the formula 8 may be obtained.

$$\begin{aligned}&(K b_1 \sigma_{b_1} e^{b_1 x} + b_2 \sigma_{b_2} e^{b_2 x}) m - \mu_g \sigma_{b_1} e^{b_1 x} \\ &- \mu_h \sigma_{b_1} e^{b_1 x} = \rho m a\end{aligned} \tag{8}$$

The formula 8 can be simplified, as shown in formula 9.

$$a = \frac{(K b_1 m - \mu_g - \mu_h) \sigma_{b_1} e^{b_1 x} + b_2 m \sigma_{b_2} e^{b_2 x}}{\rho m} \tag{9}$$

According to the Newton's laws of motion, the formula 10 may be obtained.

$$V = at \tag{10}$$

Where V = the overall motion velocity of the coal element which is analyzed, m/s; t = the time of acceleration, s.

In the whole accelerated motion process, the displacement of coal accelerated motion is the distance from the initial position to coal wall, and the formula 11 may be obtained.

$$x = \frac{1}{2} a t^2 \tag{11}$$

The coal element can obtain kinetic energy, and it may be expressed by formula 12.

$$dW_1 = \frac{1}{2} \rho m L dx V^2 \tag{12}$$

Where W_1 = the needed energy of entire coal body motion, MJ.

Putting formula 10 and 11 into formula 12, and the formula 13 may be obtained.

$$dW_1 = \rho m L a x dx \tag{13}$$

Putting formula 9 into formula 13 and the formula 14 may be obtained.

$$dW_1 = ((K b_1 m - \mu_g - \mu_h) \sigma_{b_1} e^{b_1 x} + b_2 m \sigma_{b_2} e^{b_2 x}) x L dx \tag{14}$$

The formula 15 is the integral of formula 14.

$$\begin{aligned}W_1 = {} & (K b_1 m - \mu_g - \mu_h) \sigma_{b_1} L \left(\frac{x}{b_1} - \frac{1}{b_1^2} \right) e^{b_1 x} \\ & + m \sigma_{b_2} L \left(x - \frac{1}{b_2} \right) e^{b_2 x} \\ & + \frac{(K b_1 m - \mu_g - \mu_h) \sigma_{b_1} L}{b_1^2} + \frac{m \sigma_{b_2} L}{b_2}\end{aligned} \tag{15}$$

4 THE BURST TRIGGERING MECHANISM UNDER THE COUPLING ACTION OF HIGHER STRESS AND GAS PRESSURE

According to formula 15, the thickness (m) and the width (L) are both constant to some working face, and the energy to move coal is proportional to the initial stress of coal and the additional stress generated by the release of elastic deformation energy

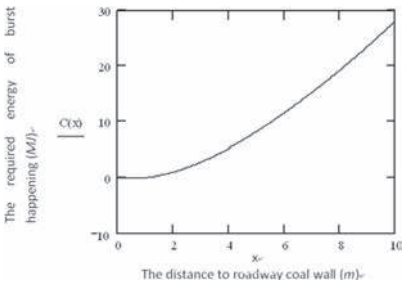

Figure 3. The relationship diagram between burst energy and burst depth.

and gas expansion energy, and it is inversely proportional to the friction stress at the top and bottom of coal seam; the relationship between it and burst depth is complicated, and it is very difficult to determine directly, and the burst energy change curve with the depth of burst can be drawn out by mathematical software, as shown in figure 3.

To coal in the condition of high ground-stress and gas pressure, because a large number of coal and rock elastic deformation energy and gas expansion energy can be released instantaneously, original stress and additional stress of burst coal is higher, and the existence of high gas pressure and crushed coal changed the frictional resistance form of burst coal, reducing friction force. According to formula 15, the energy that may be used to move coal increases greatly, and the risk of burst happening rises sharply.

The longer distance from the position of burst happening to coal wall, the higher energy required to move coal by burst, the smaller risk of burst occurrence in the same conditions. The mechanism of actual prevention measures of burst (including relieve-shot, seam water injection and hydraulic cutting seam) is increasing the width of distressed zone in the front of working face and tunnel, and the distance from the position of burst happening to coal wall is enhanced, and the energy that is consumed because of coal motion increases sharply, and the risk of burst happening falls in effect.

5 CONCLUSION

1. The mechanical model of burst coal was constructed under the coupling action of higher stress and gas pressure. In the process of bursting and moving, the relative movement between roof and coal seam belongs to rolling friction, and moreover the relative movement between floor and coal seam belongs to sliding friction.
2. In the condition of high ground stress and gas pressure, the elastic deformation energy of coal (rock) and the expansion energy of gas release instantly, not only providing enormous energy and impetus for the occurrence of burst, but also changing the mechanical action between burst coal and roof. The resistance of burst reduces, and the risk of burst occurrence rises significantly.
3. The mechanical mechanism of burst coal was analyzed in the condition of high ground stress and gas pressure, the theoretical formula of burst energy was deduced, and it increases exponentially with the burst depth; therefore, by making use of various pressure relief measures, increasing the distressed zone width, the level of energy consumption of burst happening will rise greatly, and its risk will be reduced.

ABSTRACT: In order to study the electromagnetic radiation characteristics of coal-rock-mass under strong impact loadings, the ZDKT-1type transient magnetic vibration detection system is set up in the 21180 excavating workface of TIAN AN TEN MINE in Pingdingshan Coal Group to collect the transient electromagnetic signals during the blasting process. The transient electromagnetic signals are obtained, and a pulse component is extracted from it, and then a low frequency component is gained by the Ensemble Empirical Mode Decomposition method. Based on this, the characteristics of each component and the reconstructed signal are studied. The results show that: (1) an obvious electromagnetic emission phenomenon is observed with a distance of 200 meters away from the working face during the blasting process; (2) the reconstructed EMR signal is gained by mixing the two components, the waveform presents a high amplitude pulse rising in the initial phase and then presents as a lower amplitude damp feature; (3) the pulse number of the pulse component has a good relationship with the blasting holes and blasting charge quantity, and the low frequency component has a longer wavelength, can transmit much further. Thus, both the two components have great significance for monitoring or predicting coal and rock dynamic disasters.

1 INTRODUCTION

Coal rock dynamic disasters such as rock burst and coal and gas outburst have always been major problems in coal mining. A lot of researches prove that coal and rock dynamic disaster is a result of coal and rock rupture quickly, being subject to the comprehensive action of stress and the physical chemistry inside and outside the body. Coal/rock undergoing deformation and failure emits many forms of energy, among which is electromagnetic radiation (EMR) (Wang & Zhao 2013).

The term EMR was first proposed in the 1920 (Cohen 1914), and between the 1960s and 1980s, nonlinear theoretical issues were studied, such as effects of stress on the magnetic field, electric field, magnetic induction intensity and heat induction in elastic solids and unveiled a research direction on EMR emitted by elastic media under stress (Jordan & Eringen 1964). EMR phenomenon during rock failure was found and investigated (Hanson 1982). Thereafter, several researchers studied the characteristics of EMR emitted by marble, granite and other hard rocks, and applied the EMR in earthquake forecasting (Yoshino 1989, Parrot 1989, Khatiashvili 1989). Studies on EMR produced by the deformation and failure of coal and other low strength rocks in coal-bearing strata started from 1990s (He & Liu 1995). Over the past several decades, this issue of EMR in the process of coal and rock rupture instability has aroused much concern. Many scholars have studied this issue with fruitful results. EMR characteristics, mechanism and propagation law of coal and rock material have been studied in depth (Wang & He 2009).

The experiment researches of EMR wave in the deformation and fracture process of coal under stress by slow or static load lasts ten minutes or more. Experiment results indicate that the EMR wave has a wide frequency scale. Its frequency spectrum appears as the shape of 'M' (Wang & He 2009). To study the EMR characteristics of coal under fast and dynamic loading, coal or rock crash experiment was conducted with high velocity impact at the speed over tens meters per second (Wan 2008a, b, Li & Wan 2009, Liu 2011, Li et al. 2012a). Even more, the EMR characteristics of rock mass under blasting stress wave impact was tested (Guo et al. 1999, Jin et al. 1997). The results revealed that the magnetic field varied obviously in a short distance of coal sample area during the process of coal dynamic impact, and its duration is shorter than 2 seconds and the frequency is less than 40 Hz (Li et al. 2012a).

But in the actual mining environment, the wavelength of high frequency EMR signal is so short that its propagation distance in coal and rock mass is within about 20 m (Jia 2010), and would be vulnerable to mechanical and electrical equipment of high-frequency interference effects. Low frequency electromagnetic wave has a lower attenuation in coal mass medium, could transmit much further, be well capable of anti-interference (Jia 2010).

Therefore the study on the characteristics of low frequency EMR of large scale coal-rock-mass under the impact load has great significance for the predication of coal and rock dynamic disasters. For blasting in coal mining process make coal and rock mass under intense dynamic loading, the ZDKT-1 type transient magnetic resonance detection system developed by China University of Mining & Technology (Beijing) was set up in blasting excavating work face for field test research of the EMR during coal body blasting destruction.

2 THE FIELD TEST DETAILS

2.1 *The field test system*

The ZDKT-1 type transient magnetic vibration detection system was developed for the varied magnetic field detection in the experiments related to coal and rock dynamic rupture.

It consists of magnetic field detector, signal transmit cable, and monitoring substation (underground), network switch and the host computer (on the ground). The EME signal generated during coal-rock deformation and fracture in the excavating workface is received by an electromagnetic antenna. Considering the signal is too weak and apt to be affected by the surrounding noise, an amplifier is set to amplify the forwarding gain. And then the data signal via a data collector is obtained (sample rate is 3000 s^{-1}). Then the data is transferred to an embedded computer for processing as electric current. Finally, the detector is connected to the host computer on the ground through electric cable and the network. Fig. 1 shows a schematic diagram of the system.

The detector contains 4 parts: electromagnetic signal acquire antenna, signal amplifier, data collector and embedded computer. The detector is installed on the left wall with 1.5 m over floor, and the antenna is kept towards the workface horizontally.

2.2 *Introduction of the test field*

The test was carried out in the 21180# excavating workface of TIAN AN TEN MINE in Pingdingshan Coal Group. There has been happened serious

coal and rock dynamic disasters this coal mine. The thickness of the excavated coal seam is 2.0~2.6 m, with dip angle of 6°~12°. The 21180# tunnel net sectional area is designed about 13.8 m2, and the design length is 1095 m, using blast excavating. Fig. 2 shows the layout plan of blasting holes.

The transient magnetic resonance detector is set at a permanent position staying 300 meters away from the tunnel opening. Fig. 3 shows the detector installation project plan.

The blast excavating work takes three shifts a day. Table 1. shows the record of blasting holes and other blast parameters in some excavating periods.

2.3 *The detected electromagnetic signal*

The obvious electromagnetic signal was detected by the ZDKT-1 magnetic vibration detector during the blasting process. Fig. 4 shows a detected electromagnetic signal during the blasting process.

It can be seen from fig. 4 that the magnetic field varied obviously in the area 200 m away from the working face during blasting process.

3 THE ANALYSIS METHOD OF THE DETECTED SIGNALS

Fig. 4 indicates that the detected signal contains a lot of noise so that the time domain feature is inconspicuous. In order to get the authentic EMR signal from the detected signal, the process of decomposition and reconstruction of the signal is needed.

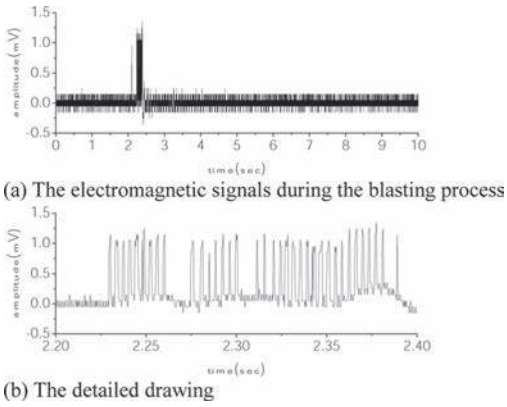

Figure 4. The electromagnetic signal during the blasting process.

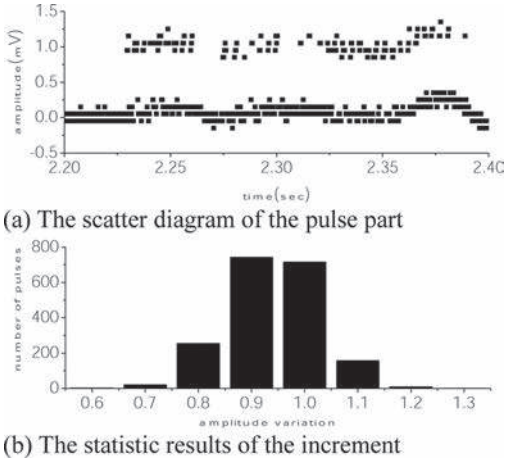

Figure 5. The increment of the pulse part.

3.1 *Extracting the pulse component from the detected signal*

The scatter diagram of the pulse part shows in fig. 5(a). The pulse part seems to have a stabile increment. To verify the hypothesis, the statistic of the increment of the pulse part in all the 27 signals has been done. Results are shown in fig. 5(b).

The results show that the value of pulse increment is still at 0.8~1.1 mV. Considering the amplitude of the noise, the real increment is 0.94 mV. For the amplitude of the pulse part presents so stable, to further observe the composition and structure of the detected signal, the pulse part should be extracted first. Fig. 6 shows the extracted results.

It is revealed from Fig. 6(a) that the pulse part focused in a short time with a stable amplitude. Contrasting fig. 6(c) and fig. 6(d), it is known that

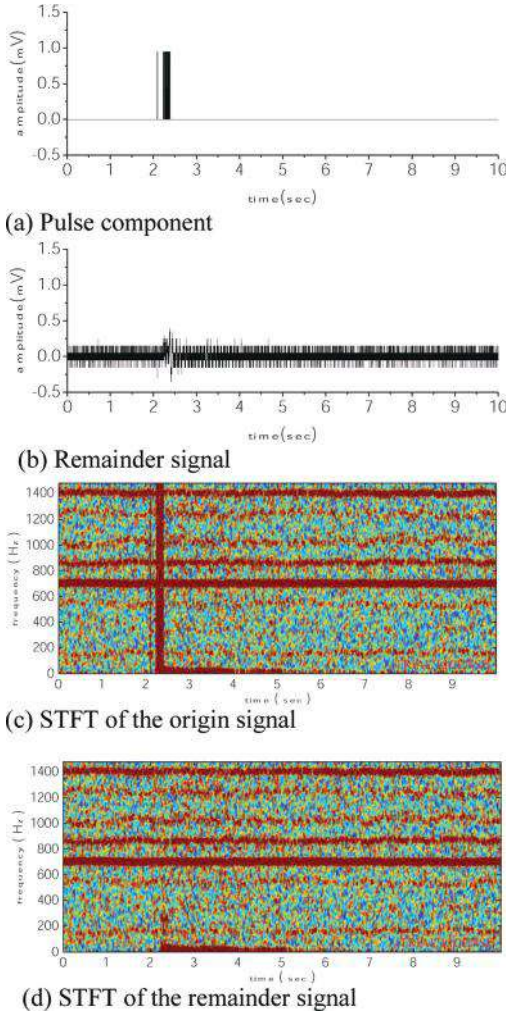

Figure 6. The pulse component extracted result.

the pulse component extract process has reduced the false frequency composition, making the remainder signal's frequency spectrum much more authentic.

3.2 *The decomposition of the remainder signal*

Fig. 6(d) emphasizes that the remainder signal greatly varies in low frequency range, but still contains a lot of noise, leading the time domain feature inconspicuous (see fig. 6(b)). Thus, the signal is paroxysmal, and its frequency and time domain statistical characteristics change over time, belonging to the non-stationary random signal. As an adaptive time-frequency signal analysis method, Empirical Mode Decomposition (EMD) has been successfully used by scholars in all fields to handle multiple nonlinear and non-stationary signals (Wu & Huang 2009, Semion et al. 2004).

Wu and Huang proposed a new concept of 'Ensemble Empirical Mode Decomposition method' (EEMD). Literature [18] has reported the detailed proceeding of EEMD method. Non-stationary random signal can be effectively decomposed into some Intrinsic Mode Functions (IMFs) by EEMD method. The valid signal waveforms of the random signal can be determined from these IMFs. These IMFs can be combined into different filters to remove the noise components or do special analyses. The low pass filter can be expressed as the following formula:

$$x_{lk}(t) = \sum_{i=k}^{n} h_i(t) + r_n(t) \tag{1}$$

where $h_i(t)$ is the IMF_i, and $r_n(t)$ is the remaining component of the decomposition.

These spatial filters preserve the nonlinear and non-stationary of the signal. And filtering and denoising or signal spectrum analyzing techniques on the basis of EEMD method have confirmed the potential superiority in many aspects, such as micro-seismic monitoring and blasting vibration signals application and the like (Liu et al. 2011, Li & Zhang 2006, Ling & Li 2004, Li et al. 2012b).

Thus, in order to obtain the authentic waveform from the remaining signal, the EEMD method was used. As shown in fig. 7, the remaining signal was decomposed into 14 IMFs from high frequency to low via EEMD, and each IMF has an independent physical significance.

As shown from the result by EEMD, IMF_h1-IMF_h4 are high energy noise components, IMF_h5 with a short abnormal part, and the abnormal part in IMF_h6~IMF_h14 are longer. There should be an index to determine which IMF could be selected as valid components. The amplitude enlargement ratio K can be defined as the judgment standard. The index K can be expressed as below:

$$K = A_1 / A_2 \tag{2}$$

where A_1 is the maximum amplitude of the abnormal part, A_2 is the normal part of the amplitude.

The K value of each IMF is shown in fig. 8.

The K value of IMF_h1 equals 1, meaning that this component hasn't changed during the blasting rupture of coal. Similarly, IMF_h2~IMF_h4 can also be seen as noise. The amplitude of IMF_h5~IMF_h14 has been enlarged more than 2 times, therefore they can be seen as the valid components of the remaining signal. The filter as formula (1) expresses can be used to mix the valid components

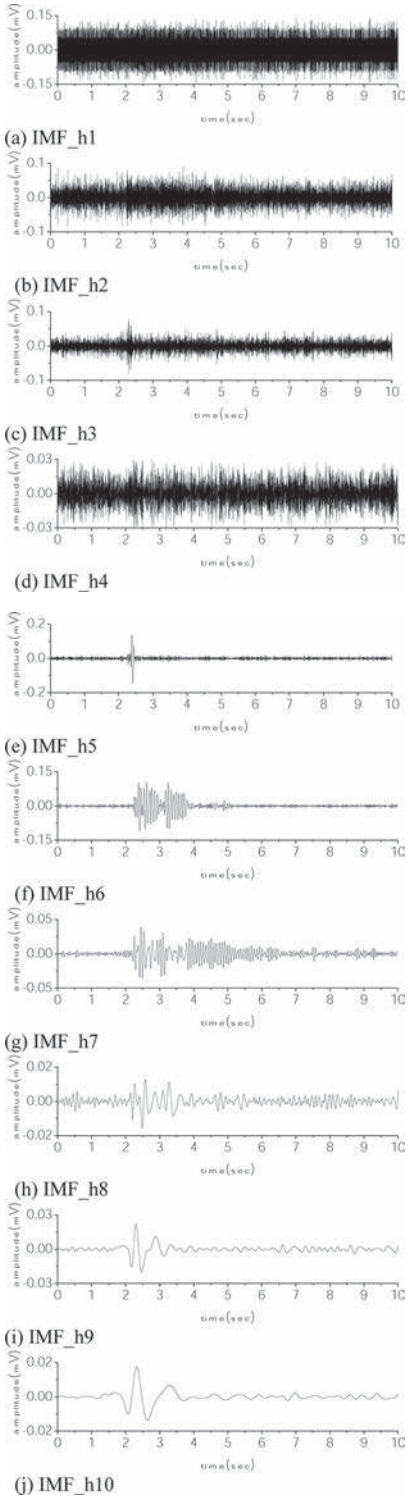

Figure 7. (*continued*).

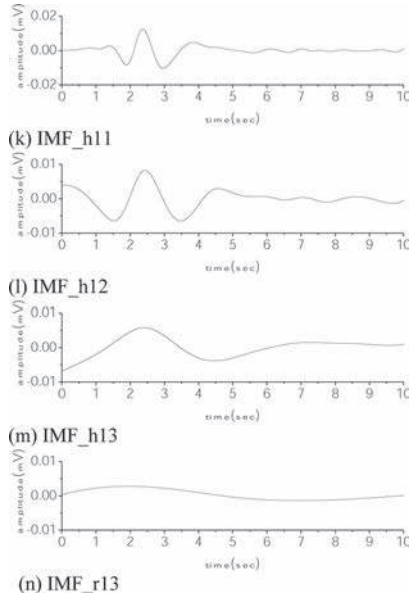

Figure 7. EEMD result of the Remainder signal.

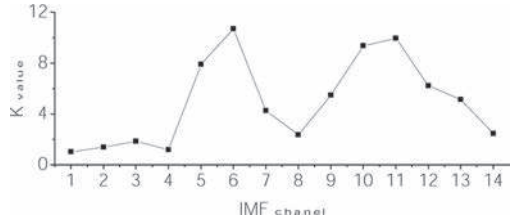

Figure 8. The K value of each IMF.

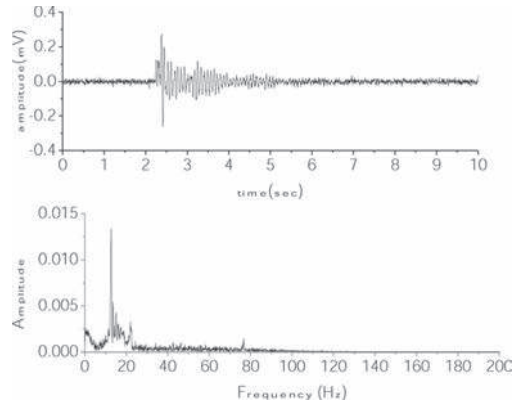

Figure 9. The waveform and FFT spectrum of the valid component in the Remaining signal.

together with another component of the EMR signal (shown in fig. 9).

Fig. 9 reveals that via EEMD method, the signal's time domain feature can be obviously distinguished, and the undesired signal can be perfectly wiped off, illustrating that the transient non-stationary nature of EMR signal detected during the coal mass blasting rupture has been fully preserved by EEMD method.

The frequency of the valid signal component focused under 25 Hz, thus this component is a low frequency EMR signal, lasting for about 3~4 seconds with a damp trend.

3.3 *Reconstruction of the EMR signal*

From the above analyses, it reveals that coal mass blasting rupture generates two kinds of EMR, pulse EMR and low frequency EMR. The two kind signals are mixed together to get the whole authentic EMR signal.

As shown in fig. 10, the reconstruction of the EMR signal waveform presents a high amplitude pulse rising in the initial phase and then presents as a lower amplitude damp feature. The method is used to other signals detected, and similar results are obtained.

4 RESULTS AND ANALYSIS

The EMR signals during coal blasting rupture process are composed by a pulse component and a low frequency component. The pulse number of each pulse component and the maximum amplitude and signal energy of each low frequency component are calculated. Table 2. presents the result calculated.

The pulse number and pulse duration have a good linear relationship (fig. 11), the slope is 0.00094, meaning the duration of per pulse is nearly 0.001s. The FFT spectrum of pulse

Table 2. The calculated result of each components.

	Pulse component	Low frequency component	
Signal Number	Pulse number	Max amplitude (mV)	Energy (mV^2)
1	39	0.19	316.50
2	7	0.07	289.84
3	40	0.27	450.11
4	67	0.25	419.33
5	64	0.24	443.60
6	11	0.18	426.87

9	16	0.13	258.73
10	14	0.19	336.35
11	3	0.12	295.23
12	7	0.12	291.23
13	25	0.14	321.66
14	62	0.31	413.49
15	44	0.21	406.06
16	35	0.15	416.47
17	27	0.26	426.52
18	19	0.34	639.86
19	4	0.14	366.00
20	25	0.19	363.15
21	2	0.12	290.82
22	3	0.12	400.28

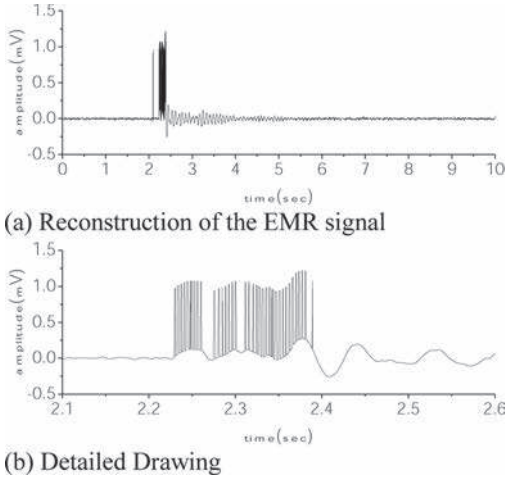

Figure 10. Reconstruction of the EMR signal.

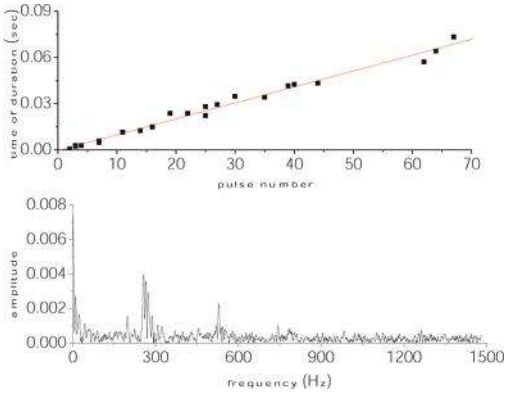

Figure 11. Relationship between pulse number and duration of pulse components and its FFT spectrum.

component indicates a wide range, but the main frequency range is focused about 250~280 Hz.

The low frequency component energy depends on its amplitude. And the maximum amplitude is related to the pulse number of the pulse component. Fig. 12 and fig. 13 present the relationship between them.

As indicated in fig. 12 and fig. 13, the maximum amplitude of the low frequency component increases with the pulse number, and has a positive relationship with its energy.

The intensity of the electromagnetic signal emerged during coal blasting process must be associated with blasting holes and charge quantity. Fig. 14 presents the relationship between them.

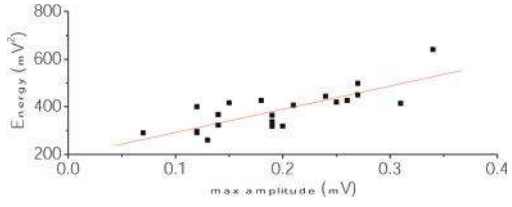

Figure 12. Relationship between maximum amplitude and energy of low frequency components.

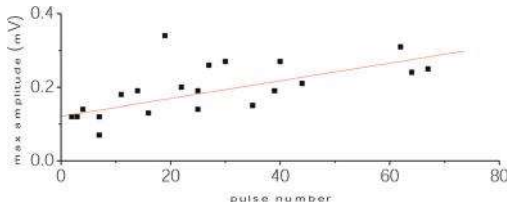

Figure 13. Relationship between maximum amplitude of low frequency components and pulse number of pulse components.

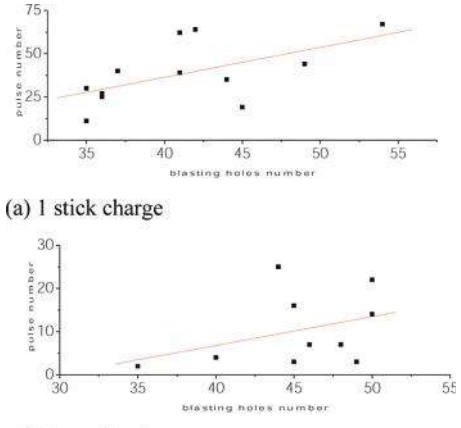

Figure 14. Relationship between pulse number and blasting holes at different charge quantity.

Fig. 14 indicates that the pulse number has an increasing trend as the number of blasting holes increases. Contrasting fig. 13 (a) with fig. 13 (b), it can be confirmed that the blasting charge quantity affects the pulse number sharply, but there exists large discreteness which need further study.

From the above analysis, it can be deemed that two kinds of EMR emerged in the process of blasting shock wave propagation in coal matrix. One is pulse radiation produced by the impact of coal or rock burst. The other is low frequency radiation caused by the rubbing effect on the coal fracture surface with the shock wave.

5 CONCLUSIONS

The field test result of EMR signal emerged during the blasting process in the excavating workface and analyses suggest that:

1. The obvious transient electromagnetic signal is observed during the blasting process with a distance of 200 meters away from the working face, and the electromagnetic signal detected can be decomposed into a pulse component and a low frequency component. When the two components mixed up to a reconstruct signal, the waveforms presents a high amplitude pulse rise in the initial phase and then presents as a lower amplitude damp feature.
2. The main frequency of the pulse component ranges from 250 Hz to 280 Hz, the duration time of a single pulse is nearly 0.001s. And the pulse number has a good relationship with the number of the blasting holes. Hence, the pulse component has much information of the impact frequency, benefits for the coal and rock dynamic disaster monitoring or forecasting.
3. The low frequency component lasts for about 3~4 seconds, with its maximum amplitude and energy related to the blasting holes and blasting charge quantity. Especially its frequency ranges about 0~25 Hz, with a longer wavelength, and can be transmitted much further. It proves that the low frequency EMR has great significance for non-contact and long-distance early warning of coal and rock dynamic disasters.

Detection method and abnormal characteristics analysis of TEM in coal mine

Qing-Hua Liang
Chongqing Research Institute of China Coal Technology and Engineering Group Corporation, Chongqing, China

ABSTRACT: Based on mine transient electromagnetic theory, combined with the mine transient electromagnetic method (TEM) detection test, this article studied detection method, abnormal characteristic and accuracy rate of mine TEM, in order to provide the reference to underground coal mine. The results showed that: mine TEM had obvious reaction to each water abnormal body, and it presented different abnormal characteristics. Based on the test statistics, the integral detection success rate of TEM was 86.2% by the analytical methods and techniques. Also, the false anomaly detection may occur, while the body containing water can be detected with this method. From the current practice experience, mine TEM may make more prediction, and rarely misses predictions. Mine TEM is a more practical geophysical method to detect water damage in the underground mine.

1 GENERAL INSTRUCTIONS

At present, to the geophysical equipment of detecting water damage in China, the geophysical equipments that can be used to underground mine mainly include Direct Current method (DC), Transient Electromagnetic Method (TEM), Ground Penetrating Radar (GPR), radio wave penetration, etc (Dong Shuning 2008). DC in space, has some unsatisfactory application effects; GPR instrument, influenced by mine explosion-proof requirements and full-ection distance is short for water damage, generally 30–50 m; radio wave penetration mainly be used to detect coal mining face. One of the advantages of TEM is that is able to penetrate the shield layer of high resistivity, plus it has better resolving power to the high resistivity layer overlying stratum or structure. It is particularly sensitive to water-containing body of low resistivity, and the range of detection is extensive (Zhang Yunxia 2004). Therefore, in recent years, it was spreaded in the application of advanced detection in China, Most coal mines are equipped with TEM devices, but the detection analysis and recognition of anomaly is not enough, Sometimes there are some analysis errors. Based on this situation, and years of experience the author, summarized TEM detecting method, studied the characteristics of each water conductivity anomaly body and application in coal mine, and examined detection accuracy rate, to provide reference for the coal mine detection.

2 TEM DETECTION PRINCIPLE

TEM is a method of detecting medium resistivity, which launches a pulsed magnetic field to the underground by the no earth return or grounding line. It observe the two induction eddy current field which are caused by underground medium using the coil or grounding electrode during a pulse magnetic field intermittently (Yue Jianhua 2003).

The basic theory of mine (full-space) TEM is basically in line with that of ground TEM. But the difference between them is that mine TEM can only be detected by multi-tum small loops, because it is used in the limited space of underground tunnel. There are certain multiples between full-space and half-space for late apparent resistivity of TEM. Therefore the late apparent resistivity of mine TEM can be calculated through the half-space TEM apparent resistivity multiplied by a coefficient K_m, mine TEM apparent resistivity ρ_τ formula is (Liu Zhixin 2008, Yu Jingcun 2007).

$$\rho_\tau = K_m \times 6.32 \times 10^{-12} \times (S \times N)^{2/3} \times (s \times n)^{2/3} \times (V / I)^{-2/3} \times t^{-5/3} \quad (1)$$

In the formula, K_m is the calculation coefficient of mine TEM apparent resistivity, and the general value is 500~2000; S is the transmitting loop area; N is transmitting loop turns; V is induction voltage; I is power supply current intensity; s is receiving loop area; n is receiving loop turns; t is the time when the second field declines. The apparent

resistivity calculated with half-space TEM is small, but it won't affect the judgment of abnormal.

3 MINE TEM DETECTION METHOD

The operating mode of Mine TEM is changeable. According to the antenna arrangement, the author classified and summarized the detection methods of mine TEM. At present, Mine TEM generally use overlapping loop device which can illustrate the work mode of underground mine antenna.

3.1 *Fixed translation method*

Fixed translation method is the detecting method which places the transmitting antenna and the receiving antenna in parallel, then moves them gradually. This method is mainly used in detection for underground coal mining working face or bottom hidden containing water.

This method is usually constructed with antenna artificially, moving once in every 5 m or 10 m till the completion of detecting the tunnel. At present, we mostly select a tunnel of coal face to detect. If the working face width is greater than 150 m, we recommend adopting two tunnels to detect, and the detection method is shown in Figure 1.

3.2 *Angle—conversion method*

Conversion angle method is the detecting method which turns the transmitting antenna and the receiving antenna at a certain angle to detect the front fan-shaped region. This method is mainly used to detect the hidden water-containing body when working on the single-entry tunnel progress.

Using this method to detect, the antenna is changed to a certain angle, generally 10°. A driving face can be changed at an angle from left to right or from top to bottom with the completion of two lines, to observe the water—containing bodies' condition in the front of driving face. In order to ensure the accuracy, the driving machine should be back more than 20 m in acquisition. Detection method is shown in Figure 2.

3.3 *Integrated method*

The so-called integrated method is a combination of fixed translation method and conversion angle-conversion method; this method mainly used when there is major water damage in front of blind tunnel.

As shown in Figure 3, we start from the left side of the driving face. Firstly, we make the transmitting antenna and the receiving antenna face the left side of the tunnel to measure up, and then rotate the overlapping loop antenna, rotating the normal direction of the antenna into a 60°, a 45°, and a 30° compared with the left side of the tunnel. According to the width of excavated section, the measuring points of which the working area is just opposite these 3 antennas are fixed. Then to the right side, measuring points are symmetrically

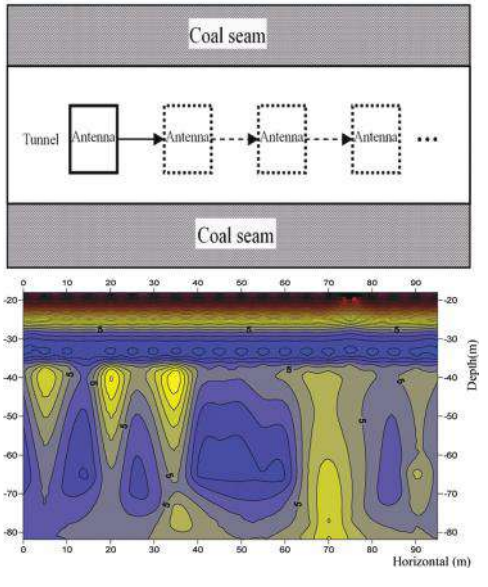

Figure 1. Schematic diagram and result map of fixed translation method.

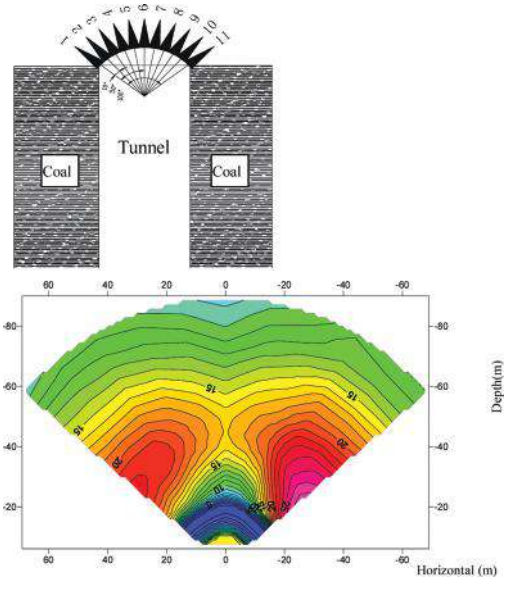

Figure 2. Schematic diagram and result map of conversion angle method.

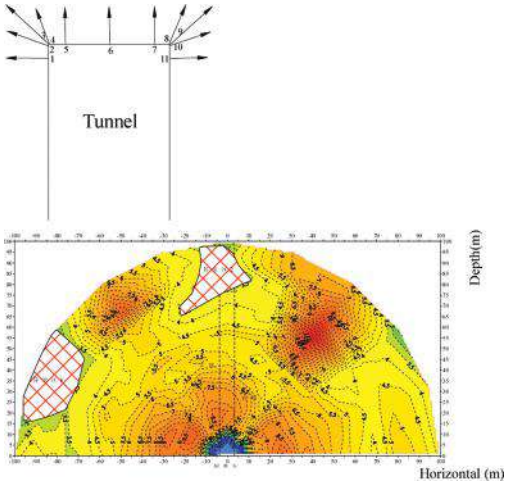

Figure 3. Schematic diagram and result map of integrated method.

arranged (Wang Dongwei 2011), so the data can be collected from multiple angles, rotation, combined with translation.

4 ABNORMAL CHARACTERISTICS ANALYSIS OF MINE TEM

In most working coal seam, the main water filling, the sandstone fracture water and limestone kart' s fissure water, the deep Ordovician limestone water and goaf water. Water channel is tectonic fracture zone and water flowing fracture in the roof caused by coal mining exploitation. The abnormal characteristics studies of fault, collapse column and goaf have a strong guiding significance for qualitative analysis of TEM abnormal condition.

4.1 *Abnormal characteristics analysis of fault fissure water detection*

In the coal mine, the fault structure in Local areas developed and the roof was broken. If the overburden is aquifer, then water in fissure will develop. Then here shows that the amplitude contour fluctuation will be increased in the apparent resistivity contour map, the change of regional variation of apparent resistivity will be larger, and there will be discontinuous small scope in low resistivity zone.

Figure 4 is the case of detecting fault fissure water in front of the driving face in Shanxi mine. From the chart, we can see that there is a small and low resistivity anomaly area located near the front of driving face 90 m. After drilling to prove, the location of the 90 m ahead is water point with low

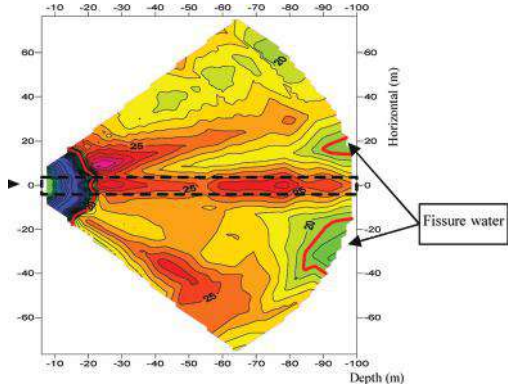

Figure 4. Apparent resistivity contour map caused by fault.

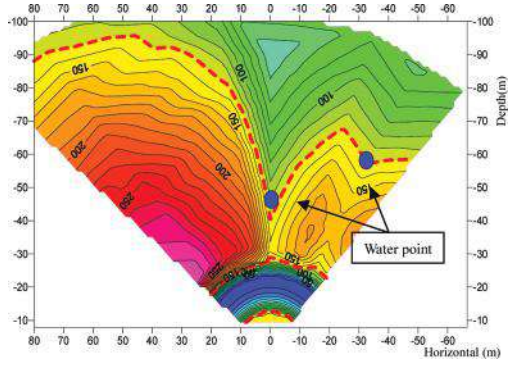

Figure 5. The apparent resistivity isopleths map when the goaf water.

resistivity abnormity which is caused by the fault fissure water.

4.2 *Abnormal characteristics analysis of goaf water detection*

In the goal water filling condition, the apparent resistivity contour shows low-resistivity in a wide range; the apparent resistivity value is associated with the containing water condition, and the continuity of low-resistivity abnormity is better. If more water was heaped up, then electromagnetic waves can't pass through, and the deep area in the contour map shows low-resistivity abnormity.

Figure 5 is a detection result map of Shanxi mine, and detecting location is return air driving face. Within 90 m in front of the detected location, there is a low-resistivity abnormity area. Located in front of driving face right ahead of 48 m, abnormal area range is relatively large and the apparent resistivity value is small. We conclude that this

area is rich of water. After verification by drilling, the water point exists in 50 m in front of the area, another water point exists in 65 m ahead on the 30 degrees right side

4.3 *Abnormal characteristics analysis of not filling water collapse column detection*

In case of not filling water, collapse column or fault crush is seriously broken with low conductivity compared with its surrounding rocks. Also it shows high-resistivity abnormity, which is reflected in the high-resistivity area of resistivity contours.

Figure 6 is an example of collapse column with no filling water in Shanxi mine, whose detecting location is track driving face. There is a high-resistivity abnormity area in front of detection area. Through verification, there is a subsided column of a diameter of 25 m and not filling water.

4.4 *Abnormal characteristics analysis of filling water collapse column detection*

In case of filling water, presents high conductivity compared with its surrounding rocks and low-resistivity abnormity which is reflected in the low resistivity area of the resistivity contours.

Figure 7 is an example of water filled subside column in Shanxi mine, whose detecting location is the air return driving face. In front of 90 m, there is an abnormal area, located right ahead of 40 to 90 m of tunneling head, in the direction of left 45 m to right 60 m.This abnormal area range is relatively large with low resistivity value, thus we concluded that it is rich in water resources. After verification by drilling, the area in front of the 46 m is water point, in addition, another water point is in the right 20 degrees ahead of 51 m of this area, which is a diameter of hydraulic 20 m subsided column.

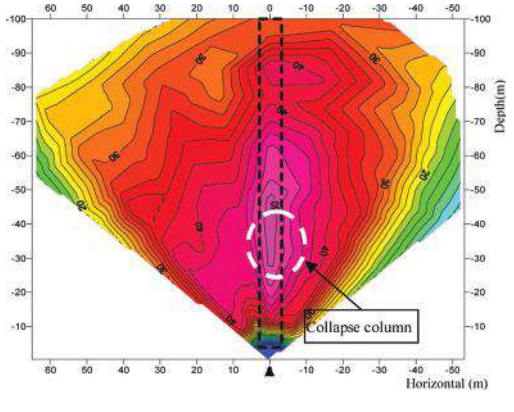

Figure 6. The apparent resistivity isopleths map of not water filled subsided column.

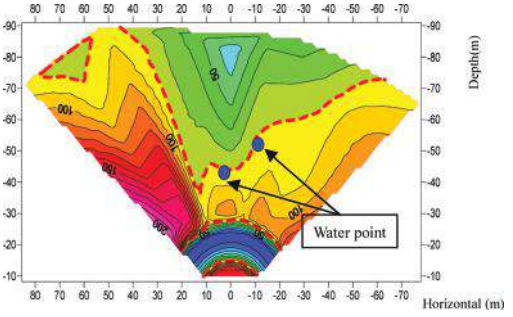

Figure 7. The contour map of water filled subsided column detecting TEM apparent resistivity.

4.5 *Abnormal characteristics analysis of water flowing fractured zone detection*

At present, the methods of determining the maximum height of coal seam water flowing fractured zone have the empirical formula method, field test method and numerical simulation method etc. The actual measurement data is the main method to determine water flowing fractured zone (Wang Shuangmei 2006). Field measurements have the mine TEM, water injection test method, ultrasonic imaging method and high density resistivity method etc.

We can study the coal mining water flowing fractured zone by mine TEM. At a certain angle detected the roof of the coal face. With the fixed translation method, we can get an overburden containing water abnormal situation of a coal mining working face. The following figure is a detecting effect chart of water flowing fractured zone in Shanxi mining coal, with 60 degrees of detection angle. From the map view, the basic abnormal area is the blue region; abnormal position exists in 52 m. Through the calculation of the triangular relationship, we can draw that the height of water flowing fractured zone is about 45 m. After the mine.

5 THE ACCURACY OF THE EXPERIMENTAL STUDIES ON MINE TEM DETECTION

Combined with the specific situation in Changping Mine Field, through the tracing detection test for mine containing water structure, this part studied the accuracy of TEM in Changping Mine.

Changping Mine is substitute of Wangtaipu coal mine in Shanxi Coal Group, the coal seams are composed of the Taiyuan group and Shanxi group. This mine now is exploited No. 3 coal seam; the problem of mine water inflow is roof water leakage and goaf seepage but no large water

damage in mine. The main hazards are goaf ponding of two village-run coal mines: Wangbao and Gaoliang coal mine which are near the southeastern boundary. We should detect and investigate on the distribution of two village-run coal mine, in order to prevent causing water inrush through the goaf seeper area.

Considering that it exist 20 m blind areas in mine TEM, We need to avoid blind areas in mine detection. After a lot of practice, we adopt the mine TEM tracking detection used as shown in Figure 9. The detection distance is 100 m, and the driving distance is 80 m; the next cycle reaches 80 m to detect. In accordance with such 80 m cycle detection, we can avoid blind area.

TEM experiment in Changping Mine started from September 6, 2011 to December 9, 2011, and a total number of TEM detection was 29 times with 2715 m prediction distance. The overall situation of abnormal test is shown in Table 1.

Through a lot of practice in mine, we got a wealth of mine TEM data. Typical anomaly of detection is showed in Figure 10.

From the analysis of table 1, abnormal frequencies of detection were 16 times; the number of

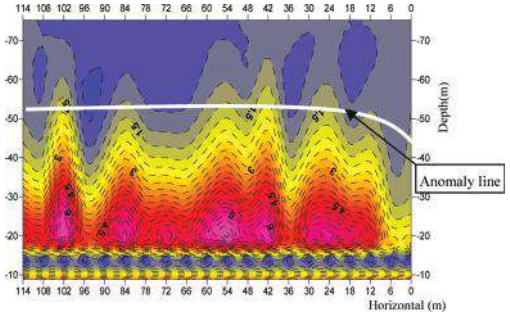

Figure 8. The sounding chart of water flowing fractured zone of TEM verification, the detection result is accurate.

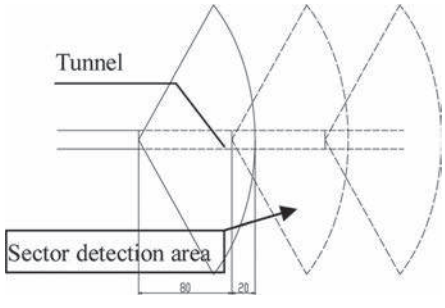

Figure 9. The track layout of sector detection the driving face.

Table 1. Abnormality detection table.

Total times of detection	Times of detected anomalies	Times of successful prediction	Times of turnover
29	16	16	0
Abnormal times	Extra times of prediction	Times of successes	Success rate of detection
12	4	29–4 = 25	25/29 = 86.2%

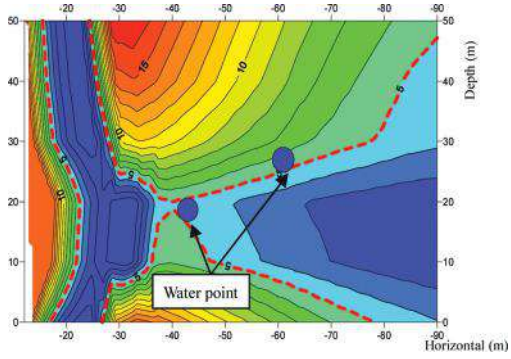

Figure10. The contour map of apparent resistivity for 13131 tunnel detection.

successful prediction was 16 times. From the total number of detection, extra times of prediction were 4 times, the total number of detection was 29 times, so the overall detection rate of success was 86.2%. From the detection accuracy of statistical data, we can see that mine TEM could present false anomaly in detecting, but this would detect basically to the existence water containing body ahead. From the current practice, TEM may forecast too much, but it rarely missing, which shows that TEM has good accuracy in coal mine application.

6 CONCLUSIONS

1. By analyzing TEM response characteristics of typical water flowing abnormal body, this article concludes that apparent resistivity contour is low resistance in a large scope when goaf or large collapse column is in the water filling conditions, and the continuity of low resistivity anomaly is better; when the small fault is in the case of water flowing, and the amplitude contour fluctuation is increased, the change of region apparent resistivity gets greater, and discontinuous low-resistivity abnormal zone exists on a small scale; abnormal body of no water flowing subsided column shows the

characteristics of high-resistivity; application of TEM can detect accurately for the exploitation of water flowing fractured zone, anomaly characteristics are manifested as anomaly low resistivity of large-area.

2. According to the arrangement of antenna, this paper summarized that the detection methods of TEM include fixed translation method, angle-conversion method and integrated method. Fixed translation method is fit for detecting in coal mining face or tunnel roof and floor, angle-conversion method and integrated method are fit for detection of driving face.
3. Through the actual verification detection to the mine TEM by the analytical methods and techniques mentioned above, the author concluded that through statistical analysis, the integral detection success rate of mine TEM was 86.2%. The detection could be false abnormity, but this method would be able to detect when it existed containing water bodies ahead. From the current practice, TEM may forecast too much, but it rarely misses a little, so it is the practical method to detecting containing water bodies in coal mine.

Calculation of the natural wind pressure of mine based on working-condition adjusted of mine main fan

Li Chen
Hebei University of Engineering, Handan, Hebei, China

ABSTRACT: This paper states the theoretical basis and application method of using the working-condition adjusting of mine main fan to calculation of natural wind pressure, and tested and verified through the practice. Compared with the traditional calculation methods, this one overcomes the error and inconvenience of the traditional ones which derives from many factors. And verifying the method by using it in the engineering case, results show that it is a theoretically feasible, computing fast, accurate calculation method to calculate natural wind pressure.

1 INTRODUCTION

Natural wind pressure is the necessary data of the mine ventilation design and technical management of mine ventilation (Liu 2003). In the use of mechanical ventilation of mine, natural wind pressure can be both main fan ventilation with power, increase air volume of mine; and may be hampering the main fan ventilation resistance, reduce the air volume of mine, reverse, and even lead to safety accident (Liu 2005). The existence of the natural wind pressure will result in changes of the parameters of the mine ventilation network (Hu & Xu 2008), and has important influence on the stability of mining area romantic (Tan *et al*. 2005). So, accurately measure the size of the natural wind pressure mine, grasp its change law, it is of important significance for the mine ventilation design and ventilation safety management.

2 CHARACTERISTICS ANALYSIS ON NATURAL WIND PRESSURE TRADITIONAL MEASUREMENT

2.1 *Partition calculation method*

It is showed in figure 1. This method is also called the direct calculation method (Hu *et al.* 2009). After the fan is stoped, set up a seal in the total wind or use the gate is closed adit wind to partition wind flow, take advantage of the differential manometer to determine the sealed adit wall or wind pressure difference on both sides of the gate, the reading of the differential manometer is the natural wind pressure in mine. This method is simple, but you need to stop the fan, it is a great influence for production and safety in mine. And

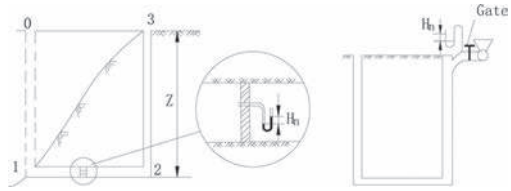

Figure 1. Calculation of the cutting airflow.

the fan is not allowed to stop, this method is inconvenient to use.

2.2 *Average density calculation method*

It is showed in figure 2. This method is also called the indirect calculation method (Hu *et al.* 2009). Through measuring the average density of roadway air flow to calculate the natural wind pressure of Mine. formula is:

$$H_n = gZ(\rho_{m1} - \rho_{m2}) \tag{1}$$

where H_n = natural wind pressure; g = acceleration of gravity; Z = height difference; ρ_{m1} = the average density of the inlet air; ρ_{m1} = the average density of the return air.

When this method is used, the fan can run normally, it does not affect the production and safety. But for the large depth, and a lot of roadway and complex ventilation system, you need to set up multiple measuring points, a heavy workload for measuring and computing is needed, and you will take a long time to measure the average density of the air. This method can not be directly concluded the natural wind pressure value of the ventilator in the multiple levels of multi loop ventilation system.

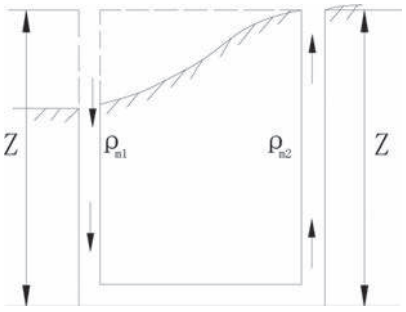

Figure 2. Calculation of the average density.

2.3 *reverse ventilation calculation method*

Using the data of the reverse ventilation in mine, according to the formula (2) to calculate the natural wind pressure of mine (Liu 2005, Liao 2013):

$$H_c = \frac{H_{yq} \cdot Q_c^2 - H_{cq} \cdot Q_y^2}{Q_c^2 + Q_y^2} \tag{2}$$

Where Q_c = mine air quantity of exhaust ventilation; Q_y = mine air quantity of reverse ventilation; H_{yq} = the relative total pressure in mine of reverse ventilation; H_{cq} = the relative total pressure in mine of exhaust ventilation.

This method needs the data of the exhaust ventilation maneuver, but the cycle of the exhaust ventilation maneuver in mine is too long, so the application of the method is restricted.

In addition, there is "Komarov" experience formula method (Bao 2000), but the error of this method is too big.

In view of the above shortcomings of the methods of natural wind pressure calculation, in order to adapt to the condition of large coal mine of natural wind pressure calculation, such as multi levels, well depth, tunnel complex, it can adjust the fan operation condition to calculate mine natural wind pressure, This method can make up the shortcomings of traditional method, realize the accurate and rapid computation.

3 THE THEORETICAL BASIS ON WHICH CALCULATING NATURAL WIND PRESSURE BY ADJUSTING OPERATION CONDITION OF THE FAN

It is necessary to adjust the operation points of the fan usually because of the changes of fan performance and the changes of natural conditions, such as the increase or decrease of the extracting coal face length, the metastasis of the extracting coal faces, the changes of gas emission. It is one of the convenient conditions to calculate natural wind pressure by working-condition adjusted of the fan.

In the mines ventilated by mechanical power, ventilation resistance of the mine is over comed by combination of the static pressure of fan and the natural wind pressure, with the joint effort of which the ventilation process is accomplished.

According to the resistance law:

$$H_n + H_f = R_m Q^2 \tag{3}$$

Where H_f = Fan's static pressure; R_n = Mine's total wind resistance; Q = Mine total air volume.

In the formula (3), H_f and Q can be measured directly, H_n and R_n are unknown. Adjusting operation point of fan, H_{1f} and Q_1 which correspond to H_f and Q can be obtained, substituting H_{1f} and Q_1 into formula (3).

$$H_n + H_{1f} = R_m Q_1^2 \tag{4}$$

Combining equations (3) and (4), and solving the natural wind pressure, that is

$$H_n = \frac{H_f - H_{1f}}{Q^2 - Q_1^2} Q^2 - H_f \tag{5}$$

The formula (5) is the theoretical basis on which calculating natural wind pressure by adjusting operation points of the fan.

In order to reduce error, the operation points of fan can be adjusted two times, three times or n times, therefore, different H_{2f}, H_{3f}, ……, H_{nf} and Q_2, Q_3, ……, Q_n can be obtained. Similarly, different equations can be obtained.

$$H_{2n} = \frac{H_{1f} - H_{2f}}{Q_1^2 - Q_2^2} Q_1^2 - H_{1f}$$

$$H_{3n} = \frac{H_{2f} - H_{3f}}{Q_2^2 - Q_3^2} Q_2^2 - H_{2f}$$

$$H_{nn} = \frac{H_f^{n-1} - H_f^n}{(Q^{n-1})^2 - (Q^n)^2} (Q^{n-1})^2 - H_f^{n-1}, (n = 1,2,3,\cdots,n) \tag{6}$$

To ensure accurate results, calculating the average for its many times, that is

$$\bar{H}_n = \frac{H_n + H_{2n} + \cdots + H_{nn}}{n}, (n = 1,2,3 \ldots, n) \tag{7}$$

4 APPLICATION PROJECTS

Now, taking the data which is tested by working-condition adjusted of fan three times in a mine

for example to describe application steps and processes which calculating natural wind pressure by working-condition adjusted of fan.

In the data obtained by working-condition adjusted of fan, extracting 3 sets of data of wind pressure and air volume, numbering and grouping them successively, dividing the data for each test into A, B, C three groups.

Combining arbitrary two sets of data like AB, AC, BC of wind pressure and air volume, substituting them into equation (5) and calculating, a set of data on natural wind pressure can be obtained. To reduce calculation error and ensure accurate results, the data can be combined many times to be calculated, and be substituted into equation (7), finally, the average value can be obtained. Calculation results are shown in table 2.

Compared with the calculation results in table 2 and the results calculated by traditional density calculation method, the comparative analysis on the error is shown in table 3.

Table 1. The performance test data of the axial flow fan in one mine.

The number of tests	The adjustment of operation condition	Sets of data	Static pressure of fan (Pa)	Air volume of fan/ (m^3/s)
1	1	A	1646.73	60.73

2	–49.032	–48.154	–1.82
3	62.978	64.234	1.96

5 CONCLUSIONS

Using the method of working-condition adjusted of mine main fan to calculate natural wind pressure of mine can make calculation convenient, time-saving and accuracy, besides, the approach has a solid theoretical foundation, it is a new mean and method to calculate natural wind pressure. It can not only test the performance of main fan in mines but also calculate the natural wind pressure of mine, to be more important, it can provide accurate basis for management of ventilation equipments.

The data must be integral and rational when using the working-condition adjusted of main fan to adjust data. To ensure the accuracy of the results of natural wind pressure, a few more sets of data can be chosen to calculate respectively, finally, the average value can be obtained.

Study on new hydraulic support and technology of top-coal caving at the ends of fully-mechanized working face

Yude Liu
Key Laboratory of Mine Disaster Prevention and Control, Yanjiao, Beijing, China
College of Safety Engineering, North China Institute of Science and Technology, Yanjiao, Beijing, China

ABSTRACT: Based on the top-coal caving fully-mechanized working face No. 43B2 at Wangzhuang Coal Mine, we have analyzed the moving law of overlaying strata above the ends of working face, and determined the relationship between the end-support and surrounding rock, and designed the new top-coal caving hydraulic end-support i.e. the host-vice transitional inner-end-support and the symmetric end-support, and then mathematical simulated and analyzed the caving character of top-coal at the ends of working face. We have solved two key problems in the design process of end-support; one is that the end-support has enough space to place the rear conveyor of working face, other one is that the loose drop-coal on the floor can be carried into the high troughs of conveyor head and tail. The core content of new end-support includes the low coal-raking system which has the tilt scraper and the symmetric pair wheels and the high coal-caving system which has the unsymmetrical pair-open troughs. It should improve the coal recovery significantly, produce good economic and social benefits, and have very important significance and broad application prospect that to solve the difficult problem of top-coal caving at the ends of fully-mechanized working face.

1 INTRODUCTION

Since 2000, the fully-mechanized top-coal caving mining technology has become main method of thick coal seam in China which has basically instead of the fully mechanized layered mining and its application range is growing.

At present, the recovery rate of top-coal caving mining is not high, is relative less than of layer mining. The loss rate which makes the recovery rate of fully mechanized top-coal caving working face to be averaged 81~83% contains process loss about 7~12%, initial and ending cutting loss about 1%, two ends loss about 4~5%.

The layout of head, tail and transmission device of front and rear conveyors needs a large support space and high support strength, and makes the process more complex. On the other hand, the ends of working face are more difficult to maintain at the condition of top-coal caving. So the ends of fully mechanized top-coal caving working face used to be support by no-caving or less-caving traditional support mode such as individual hydraulic prop, bolt supports, common hydraulic supports or transitional supports and so on.

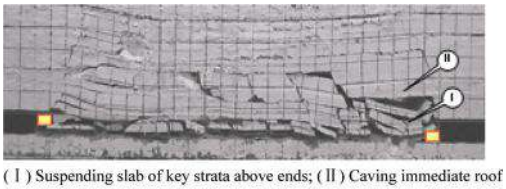
In order to achieve the purpose of high production and efficiency, it is inevitable trend that using hydraulic end-support at ends of working face which can be put down top-coal and favorable support. Therefore end-support can produce remarkable economic and social benefits, has very important significance and broad application prospect.

2 RESEARCH FOUNDATION

The fully mechanized working face No. 43B2 which is buried depth of 237~256 m exploits 3# coal seam. This coal seam deposits in Shanxi Group of Permian system, is thickness of 7.4 m and an average angle of 3.5°. The rock character of roof and floor can be seen in Figure 1.

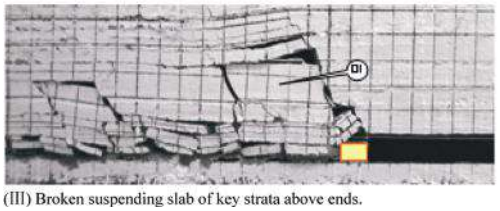
Serial number	Roof and floor	Average layer thickness /m	Histogram	Strat name	Petrographic description
1	Basic strata	3.70		Fine sandstone	Gray, fine grain, composition of quartz, feldspar. Contain mica piece.
2	Immediate roof	3.30		Mudstone	Black, compact, and including a large number of plant fossils
3	Coal seam	7.40		3' coal seam	Coal seam structure /m 0.55 (0.05) 0.29 (0.22) 4.08 (0.06) 0.53 (0.12) 0.8 (0.03) 0.67
4	Immediate floor	0.90		Mudstone	Black, compact, and including plant fossils
5	Basic floor strat	1.60		Fine sandstone	Gray, fine grain, composition of feldspar, quartz. Contain mica piece.

Figure 1. Strata histogram of working face No. 43B2.



The ratio of mining and caving is 1: 1.3, and the caving step distance is 0.8 m. The working face's roads are supported by the combined support mode of bolt and anchor-cable. The hydraulic supports among working face are ZFS-6000/17/33 type, are amount of 131 supports in the longest section of working face. Three supports are laid at each end of working face which is 6500/20/32 type.

3 STRUCTURE CHARACTERISTIC ABOVE THE ENDS OF FULLY-MECHANIZED TOP-COAL CAVING WORKING FACE



After top-coal caving, above the ends there is a certain area of hanging slab which is periodically broken and hinged joint to rock-mass of goaf along with the advancing of working face.

This is shown in Figure 2.

Above the ends of working face, the roof strata can form a structure of arc triangle suspension slab which is as shown in Figure 3, and be supported mainly by the ends' supporting, coal wall front of working face, waste rock rear of working face, and protective pillar of roadway.

(I) Suspending slab of key strata above ends; (II) Caving immediate roof

(III) Broken suspending slab of key strata above ends.

Figure 2. Caving characters of overlying strata above the ends of fully-mechanized top-coal caving working face.

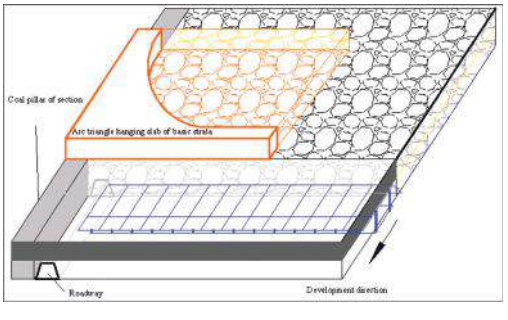


Figure 3. The structure of arc triangle hanging slab above ends of working face.

Therefore at the conditions of top-coal caving, there may be two relations as follows between supports and surrounding rock:

a. "Supports and cracking rock" structure: the triangle suspension slab has hinged structure with the fracture rock inside goaf. Under the cover of slab, the collapsed loose body of immediate roof and coal may pile up on the supports naturally.
b. "Supports and cracking rock and rock beam" structure: The fractured arc triangle slab, which its' two ends hinge to the fracture rock of goaf and the no-broken rock strata above the pillar of roadway, forms a monoclinic hinged structure.

4 NEW HYDRAULIC END-SUPPORT OF TOP-COAL CAVING AT ENDS OF WORKING FACE

According to the falling features of overlying strata and top-coal above the ends of working face, we have developed the new hydraulic supports which can make the top-coal to cave at the ends of working face. The collocation mode of those supports is as shown in Figure 4.

4.1 *Key problems*

To achieve the purpose of top-coal caving at the ends must solve two key problems:

a. End-support has enough space to place the rear conveyor.
b. The loose cracking coal on floor can be carried into the troughs of conveyor head and tail.

4.2 *Host-vice type transitional inner-end-support*

The stereo effect of transitional inner-end-support is as shown in Figure 5.

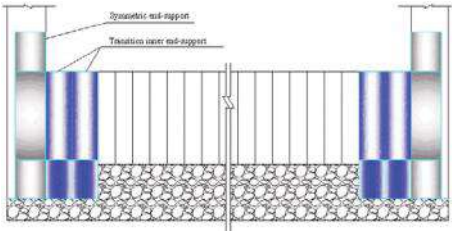

Figure 4. The layout of new end-supports at ends of working face.

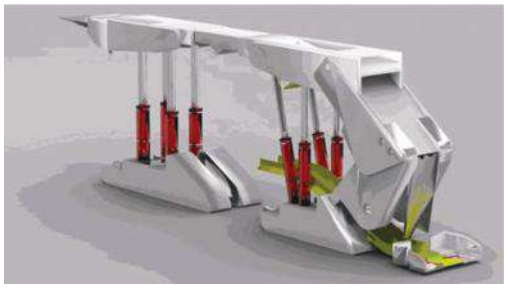

Figure 5. Virtual effects of host-vice type transitional inner-end-support.

4.2.1 *Host-vice type*

It makes the rear scraper conveyor to locate in a larger space that adding a vice support behind the normal (host) support. See Figure 6.

4.2.2 *Low coal-raking system*

The coal-raking system with tilt scraper and symmetric wheels is put under the low coal-caving window, rakes the cracking drop-coal on the floor into the high troughs of scraper conveyor's head and tail.

The system consists of high segment, middle segment and low segment. The low segment is joined to the base of supports. The high segment hinges to the trough ledge of scraper conveyor in the way of sliding round, and hinges to the middle segment in the turn way. The dip angle of the middle segment isn't more than 25°. See Figure 7.

4.2.3 *High coal-caving system*

The coal-caving system with unsymmetrical pair open troughs (one longer and one shorter) is designed in the middle of support's top beam. The open troughs joins to support's top beam in the way of sliding round, in order to adapt to the continuous caving of top-coal at different location of scraper conveyor.

The single open directional moving baffle plate is installed at the side of shorter trough, in order to improve the efficiency of coal loading, while at the same time the fixed baffle plate is installed at one trough ledge of scraper conveyor. See figure 8 shown.

4.3 *Symmetrical-type end-support*

Base on the host-vice transitional support, it is consisted of similar symmetrical end-support that to add an inverted part of support at roadway area. The virtual effect of symmetric-type end-support is as shown in figure 9. Its principle and size data of the low coal-raking system and the high coal-caving system are basically same as the transitional inner-end-support.

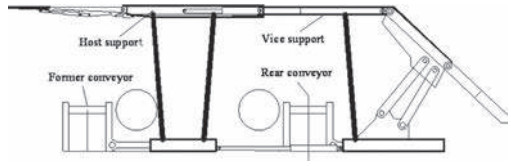

Figure 6. The space relation between supports and conveyors at ends of working face.

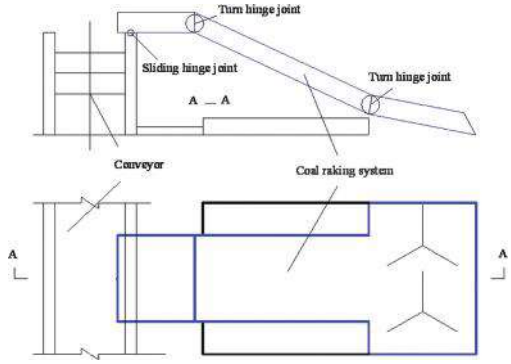

Figure 7. The coal-raking system with tilt scraper and symmetric wheels.

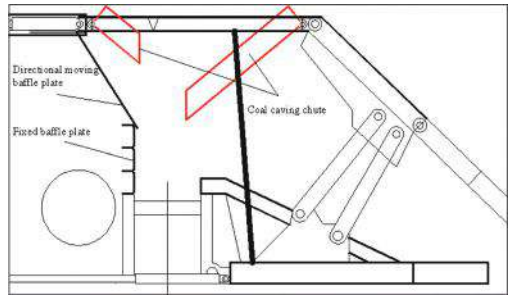

Figure 8. The coal-caving system with unsymmetrical pair open troughs.

Figure 9. The virtual effect of symmetric type supports at ends of working face.

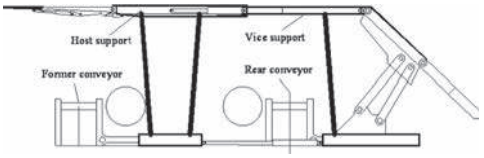

Figure 10. The structure of symmetrical end-support.

The inverted part of support plays an advance supporting role to improve processing efficiency, safety and reliability of the working end; on the other hand, improves the stability of overall support, see Figure 10.

4.4 *Basic parameters*

4.4.1 *Working resistance*

The reasonable working resistance of support can be calculated by Load Estimation Method and Theoretical Analysis Method.

The need working resistance of support is as follows by Load Estimation Method:

$$P_1 = 642.32 \times 9.0 \times 1.5 = 8671.32 \text{ kN} \quad (1)$$

While, the need working resistance is as follows by Theoretical Analysis Method:

$$P_2 = 5939.4 \text{ kN} \quad (2)$$

Therefore, the support resistance of new hydraulic end-support of fully-mechanized top-coal caving working face should be more than 8672 kN/frame.

4.4.2 *Initial support force*

Initial support force should not be too big, generally is not less than 60% of working resistance.

According to the geological conditions of Wangzhuang Mine, the initial support force takes 80% of working resistance of new end-support i.e. 6937 kN/frame.

4.4.3 *Structure height*

The height of end-support may be determined by the structural thickness of coal seam. According to the domestic experience and the size of basic supports in 43B2 working face, the minimum support height of new end-support is 1.90 m, and the maximum is 3.90 m.

4.4.4 *Structure width*

According to the theory and mining practice of top-coal caving, the short axis Lb of ellipsoid in top-coal caving space can be calculated by the following formula:

$$L_b = (0.15 \sim 0.21)\, h \quad (3)$$

In the formula: L_b is ellipsoid's short axis, m; h is the top-coal caving height, m.

To take the condition of 3# coal seam into the formula gets the conclusion:

$$L_b = 0.585 \sim 0.819 \text{ (m)} \quad (4)$$

The reasonable support width and caving step distance should be integer times of L_b in order to achieve the maximum limit of top-coal caving. So, the width of new end-support is chosen to 1.75 m.

5 ANALYSIS OF TOP-COAL CAVING CHARACTER AT WORKING FACE ENDS

It is calculated and analyzed by UDEC3.0 software that the six main influence factors of top-coal caving character i.e. the mining-caving ratio,

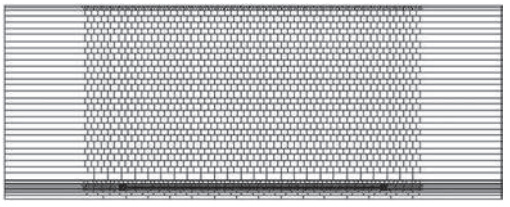

Figure 11. The model of numerical simulation.

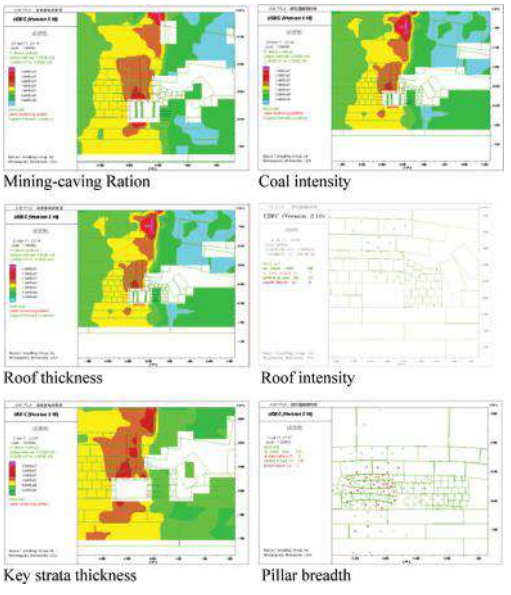

Figure 12. Some demonstration of mathematical simulation results of top coal caving characteristic at ends of fully-mechanized working face.

Table 1. The influence law of top-coal caving at ends of fully-mechanized working face.

Effect factor	Simulation scheme	Influence law
Mining-caving ratio	1:1, 1:2, 1:3 (Coal thickness is 7.4 m).	The ratio of mining and caving height is the bigger, and the caving of top coal at ends is the better.
Coal intensity	f = 1.5, 2, 3, 4 and 5 (Mining-caving ratio is 1:2).	The Coal intensity is the bigger, and the caving of top coal at ends is the more poor.
Roof thickness	38 m, 28 m and 4 m (mining height is 7 m).	When the immediate roof thickness is not enough to be full of the goaf, the immediate roof thickness is the bigger, and the caving of top coal at ends is the weaker. Otherwise the thickness of immediate roof has less action on the top-coal caving.
Roof intensity	20 MPa and 30 MPa (coal intensity is 20 MPa).	It goes against the top-coal caving that when the immediate roof strength is less than coal seam strength, otherwise is in favor of the top-coal caving. And it makes the immediate roof and top-coal to deform and destroy integrally that when the immediate roof strength equals to coal seam strength.
Key strata thickness	3 m, 4 m and 8 m (roof thickness is 4 m).	The key strata thickness is the bigger, and the carrying capacity of key strata's arc triangle slab at ends is the stronger, and the caving of top-coal is the weaker.
Pillar breadth	No mining; leave lane along goaf; pillar breadth is 5 m, and 30 m respectively.	The breadth of coal pillar is the smaller, and the breakage of top-coal is the more serious, and the caving of top coal is the easier, and the support of ends is the more difficult.

immediate roof thickness and strength, key strata thickness, coal seam intensity, coal pillar width etc. The numerical calculation model is shown in Figure 11. Its floor boundary is vertical fixated, and both side boundaries are horizontal fixated. Material constitutive model is Moore-coulomb model.

The simulation process is as follows: from the equilibrium calculation of original rock stress to the calculation of bolt support along with roadway excavation, then to the cutting advance of top-coal caving working face, and to the output of result. Part of the calculation results is shown in Figure 12.

The top-coal caving law at the ends of fully mechanized face can be obtained by summary of simulation results, and seen Table 1.

6 CONCLUSIONS

New top-coal caving end-support has the coal-caving system and the coal-raking system. This end-support is an innovation of top-coal caving hydraulic support, and can improve the recovery of coal, and make the distinct economic and social benefits.

At the condition of top-coal caving, the overlying strata can form the arc triangle slab which may break periodically at the ends of working face.

By the application and observation of top-coal caving at the ends of 43B2 working face, it is known that the periodical pressure step is average of 14.3 m, and the biggest incidence is average of 2.05 m, and the excessive amount of recovery coal is 54966.6 t, and the recovery rate is improved about 5.8%.

Study of reliability of on-line monitoring system for mine hoist braking system

Hong-Bing Qiao, Kai Liu, Yi-Lun Wang & Hua Yu
China University of Mining and Technology (Beijing), Beijing, China

ABSTRACT: The reliability of the mine hoist braking system, directly determines the coal production safety and worker safety in the hoisting transportation process. This paper proposes an on-line monitoring system of mining hoister braking system based on fault tree analysis, which sets up the fault tree of the mine hoist braking system and determines the monitoring points. We design the on-line monitoring system of mining hoister braking system based on Siemens's PLC. The monitoring system capable of providing on-line monitoring and providing HCI (Human-Computer Interaction) can be used as the assisting tool of running and maintenance of the hoister.

1 INTRODUCTION

The reliability of the mine hoist braking system, directly determines the safety of workers in the process of transportation. Relevant data show that coal mine safety accidents caused by the braking system failure account for over 60% of the total mine accidents, having caused great economic losses and casualties.

More and more enterprises want to be able to schedule maintenance in time, to realize the predictive maintenance, to manage the equipment more effectively, to curb accidents, and improve the comprehensive benefit of enterprises according to the braking system the real-time state of work. Therefore, mine hoisting mechanism system real-time monitoring equipment based on modern monitoring technology must be developed. The traditional mechanism of hoist braking system can judge one single limitation. When the abnormal occur, simple alarm instructions come into use. This pattern cannot systematically, scientifically reflect the reliability of the mechanism of the whole hoist braking system so that great potential safety hazard exists in the production process. The comprehensive evaluation of the reliability of the hoist braking system should be employed, thus establishing fault tree of the mechanism of hoisting braking mine system security to determine various monitoring points.

Using Siemens PLC as the core, designs the real-time monitoring system of the hoist braking system, which can be used as a staff member to management and maintenance of auxiliary hoist analysis tools. The main features include real-time online monitoring, human-computer interaction interface.

2 FAULT TREE OF HOIST BRAKING SYSTEM

2.1 *Modeling of the fault tree analysis of braking safety system*

Insufficient braking torque is the major failure of mine mechanism dynamic system through summarizing dynamic failure caused by the mine accident reasons of the hoist braking mechanism. All the fault parameters of each parameter is not isolated, but interrelated and interacted in the braking process. Fault tree analysis is intuitive, flexible, convenient and universal, especially suitable for the failure analysis and research of braking system. Therefore, by using the fault tree analysis method in this paper, deduce the braking safety failure events graphically, analyze and reason the system fault and failure of the system components relates in together organically, find out all the reasons causing brake failure, evaluate the reliability of braking system. (Zhang 2007).

2.2 *The determination of monitoring points*

To determine the reasonable monitoring point is the key to the successful monitoring system, all other work is for its services. Reasonable monitoring stations can be determined through shoe safety fault tree analysis and the point of geometric and physical relationship. Indirect monitoring points are derived from the direct transformation of monitoring data.

Experience reference points are determined by the experience of the field specialist.

Indirect monitoring: shoe clearance (4 groups), brake shoe wear and tear (4 groups), state of

spring (group 4), temperature rise rate of brake rubber blocks (4 groups), change rate of the working oil pressure, oil pump reaction time (2 groups), export/working oil pressure differential, the deflection of brake disc, symmetrical gap (4 groups).

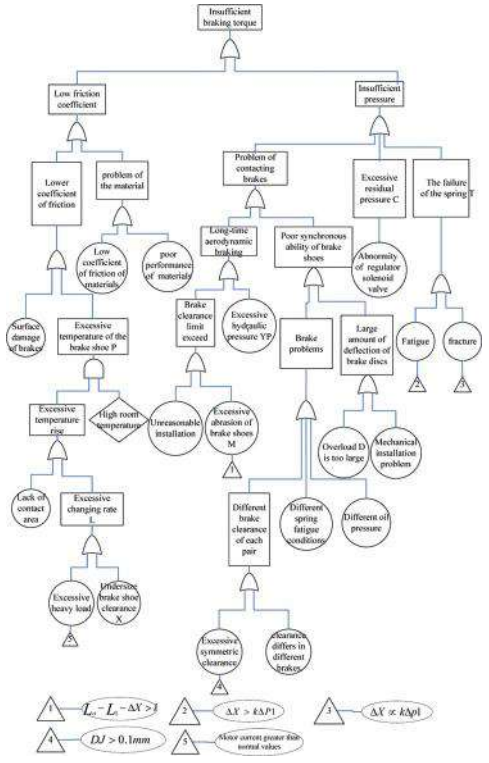

Figure 1. The Security fault tree of hoist braking system.

Experience reference points: shoe quality, spring time, installation of brake shoe, brake disc.

The nature of the brake-shoe is easy to loss, which directly indicates that the block has the characteristics of real-time relative variations. Clearance of the brake shoe is a very active parameter. The deflections of brake disc, the oil pressure of the hydraulic pressure station and degree of the fatigue and damage of the disc springs also have effects on it. The direct reaction in the braking system is reflected by the performance of the brake shoe clearance. So the clearance of the brake shoe is the key parameters of safety of real-time monitoring of brake shoe.

Mathematics and physics relationship between Indirect monitoring points and direct monitoring points monitoring are as follows:

Brake clearance: L; Brake shoe clearance: X = L.

Symmetrical clearance: DJ = Xa – Xb

Xa/Xb are same set of brake shoe clearance respectively.

$$\begin{cases} \Delta X = k\Delta P1 \\ \Delta X = \chi_n - \chi_1 \end{cases}$$

Spring deformation caused by difference of oil: ΔX

ΔP1 = P1n–P11, P1n, P11 are the working oil pressure when the brake loose brake at 1/n times respectively; x1, xn are brake clearance when loose the brake after braking at 1/n times respectively.

Disc spring deformation:

$$T = \begin{cases} \Delta X > k\Delta P1 & (\text{Spring fatigue}) \\ \Delta X \propto K\Delta P1 & (\text{Spring fracture}) \end{cases}$$

Differential pressure: JP = CP – YP YP is the hydraulic station when brake is in loose condition.

Table 1. Direct monitoring points.

Monitoring points	Monitoring sensor type	Sensor installation
Brake clearance L (4 groups)	High-frequency eddy current sensor	Sensor installed on the brake block, surface parallel to the brake shoe back
Skin temperature of brakes (4 groups)	Infrared temperature sensor	
The oil pressure of the hydraulic pressure station YP	Hydraulic sensor	The installation of main loop of the hydraulic station
Safe brake hydraulic pressure on Level 1 ZP	Hydraulic sensor	Pipeline of spring energy accumulator in tube B
Hydraulic pressure of hydraulic station export CP	Hydraulic sensor	Installation of the hydraulic pump inlet
Load current D	AC current sensor	Ammeter circuits
Oil temperature of the Tank YW	Thermocouple	Installation of the tank
Room temperature	Thermocouple	

The residual pressure: oil pressure in the hydraulic station when braking.

The deflection of brake disc: PB = MAX(ΔX), ΔX is for the clearance of symmetric brake shoes.

Temperature rise of Brake shoe: S = J – W.

Temperature rise rate of brake shoe: L = S/t1, t1 is sampling time.

Rate of oil pressure change in hydraulic station: YPL = ΔYP/t2, t2 is the sampling time.

3 DESIGN OF MONITORING SYSTEM

3.1 *Design of system function*

This system can be used as management and maintenance of auxiliary analysis tools of hoist machine for the staff, so as to curb major accidents and prolong the service life of equipment, and ensure the normal production. The purpose of its main features includes real-time online monitoring and human-computer interaction. (Qiao et al. 2010).

3.1.1 *The function of the real-time online monitoring*

Monitoring system requires for real-time monitoring on the mechanism of dynamic system, and processors are applied to collect data for analysis, judgment. When the clearance of brake-shoe exceeds the specified value or the symmetrical clearance of brake-shoe exceeds threshold value or hydraulic pump station works abnormal, various kinds of fault conditions can trigger alarm or forecasting warning. This has the following functions to the coal mine production work:

1. Remind staff in a timely manner to adjust and repair the equipment, ensures reliable braking brakes, and ensure safety in production enterprises.
2. Ensure brake-shoe clearance and Symmetrical clearance of each pair, to guarantee the braking stability, so as to prolong the life of the hoist mechanical system, reduce the major security incidents caused by the damage of roller and reducer. At the same time, for real-time and high precision monitoring of brake shoe wear and tear, it can replace mechanical switch for wear of brake shoe.
3. Ensure the reliable operation of the hydraulic pump station, make the staff in a timely manner to maintain and improve its reliability and service life.

3.1.2 *The human-computer interaction interface function*

In order to highlight the principle of "people-oriented", humanization interface is set up to facilitate staff to maintain and manage the mine hoist. It provides staff with comprehensive, intuitive information, to ensure that the hoist system for efficient maintenance and management.

3.1.3 *The selection of the main controller*

Main controller is the core of the monitoring system, which determines the design of the hardware system and software system the whole monitoring system of. So the type of main controller should be firstly determined, and then to determine the implementation scheme of the whole system based on the selection of main controller. Currently, microcontroller, DSP and programmable controller (PLC) is widely used. Having compared the performance of the three, PLC facilitate to the subsequent development of system, is more suitable in the mine production environment. So PLC is elected as main controller system.

3.2 *Design of the hardware system*

The designs of hardware system and type selection directly influence the overall performance of the system. This section details design principles of the hardware circuit, aiming at the need of function of the modular design. Touch screen with PLC is used as the main scheme, and it introduces the selection of the main function module, performance and advantages.

3.2.1 *The CPU module*

S7–200 series PLC is developed and produced by Germany's Siemens Company, which is a small modular PLC with stacked structure. PLC S7-200 PLC not only has the basic control functions, but also characterized by compact structure, low cost, strong communication and network. It can be applied for simple control situation, suitable for the complex automatic monitoring and control system; can also make network control system, which has the very high performance price ratio. The model number of this article chooses—CPU226 is the most advanced CPU of S7-200PLC series. (Chen 2009).

3.2.2 *The main function module*

System configuration is the first step in using PLC. It is the key step of allocation of appropriate systems to give full play to the function and effect of PLC to achieve better economic benefits. The CPU module, power module, memory and extension module should put into comprehensive consideration when carrying on the system configuration. It neither lost any item in system configuration, but also is higher than the user's actual requirements.

3.2.3 *Selection and installation of sensors*

According to the specific purpose, objects and environment, selecting the appropriate sensor is the primary problem when measuring a certain value. Effect of the measurement depends largely on whether the selection of sensors is suitable.

1. Considering the working environment and the actual condition of mine production, where the characteristic is full of dust, high variation in relative temperature and humidity, this article selects the high precision non-contact eddy sensors to ensure the accuracy of measurement. This type of sensor is divided into high frequency reflection type and low frequency transmission type two kinds. Considering the object to be tested—the physical structure of disc brake, high frequency reflection type is optimal. (Wang 2004).
2. The system selects the IRTP series sensor to monitor the temperature of the brake shoe. IRTP sensor series are economical temperature sensors. Monitoring accuracy is not affected by pollution, moisture and the influence of electromagnetic interference environment.
3. HYDAC ETS4000 series temperature sensor is chosen for the oil temperature.
4. Hydraulic sensor selects CYAT type pressure sensor, which has high measuring accuracy, stable and reliable performance, good sealing performance.
5. Use thermocouple to measure the hydraulic oil temperature and room temperature.
6. We choose HB1701S series DC power supply produced by Shanghai FUJIDQ electric company as system sensor power source. The output voltage can be freely chosen from 0~30V, and output current can be continuously adjusted within 0~30 A.

3.3 *Design of the software system*

PLC of S7-200 series apply software STEP7-Micro/WIN32 software to complete programming, alignment, and online monitoring.

3.3.1 *Design of the sampling programs*

Monitoring points of monitoring safety system of the mine hoist use signal sampling process shown in figure 2, to reduce the errors affecting the decisions of the system.

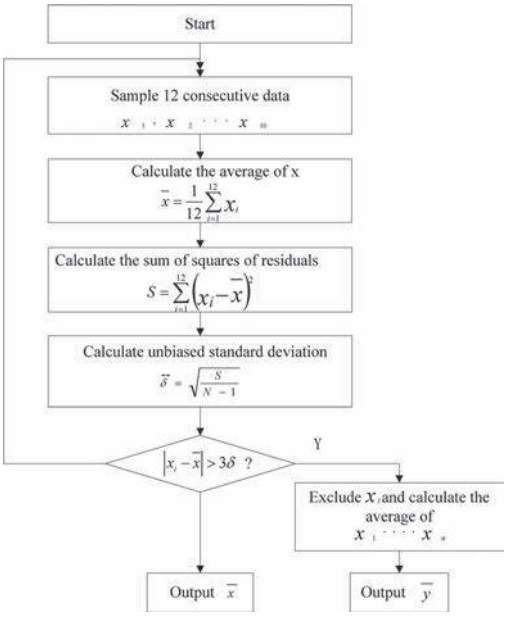

Figure 2. Signal sampling process.

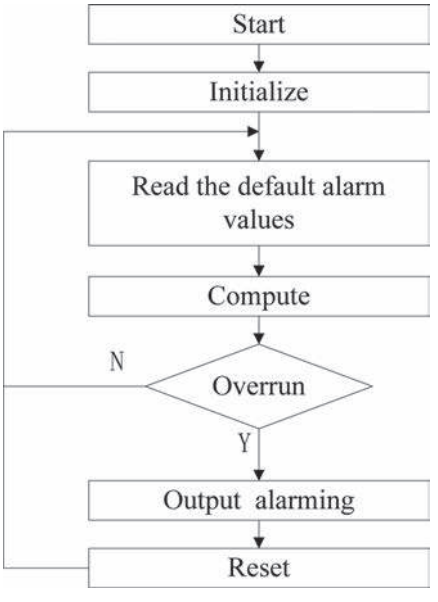

Figure 3. The main flow of alarming.

3.3.2 *Design of the alarm system*

Alarm program for braking safety monitoring system is very important. PLC system is required for logic operation and it sends the signal into human-machine interface. According to the relationship of direct monitoring points and indirect monitoring points, the state of alarms can be determined. It includes the following aspects: the brake clearance alarm, residual pressure alarm, oil pressure alarm, disc spring state alarm, excessive brake shoe wear alarm, oil filter state alarm, brake shoe temperature alarm, the oil temperature alarm, over-

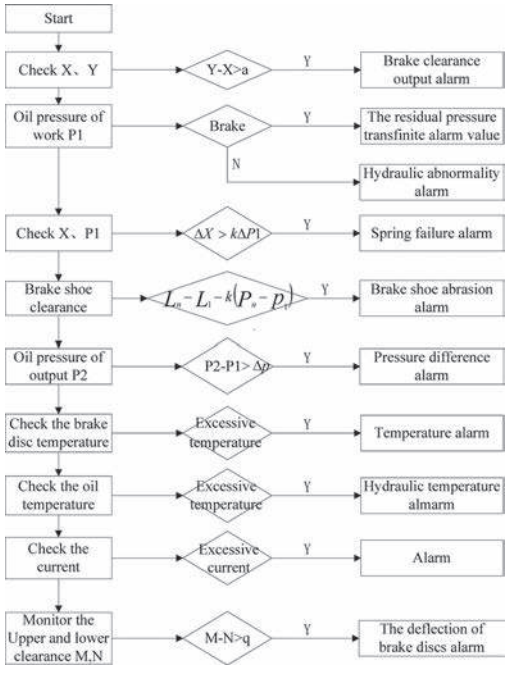

Figure 4. The flow of alarming.

load alarm and deflection of brake disc overload alarm.

3.3.3 *Design of man-machine interface*

Man-machine interface development environment of the brake safety monitoring system:

SIMATIC WinCC Flexible is a kind of innovative HMI software under Windows, which is used in control and automated monitoring process in the factory. All this engineering software allows for configuration in operator panel based on SIMATIC HMI (Windows) - from the control panel of minimal solutions to the PC. (Shijian Luo & Shouqian Sun 2002).

Brake safety monitoring system of human-machine interface mainly includes display, query functions, operating permissions. Show features include display parameters of monitoring system in real time, display and indicated the situation of braking system failures, historical curve of monitoring parameters. Query function is able to refer the braking system failure records at any time. Operation permissions is set up in order to ensure relevant staff only to view or modify the information of the monitor system, such as settings of the alarm values.

Study on the prediction model of gas emission for coal beds based on the EMD and BP-ANN

Li-Ning Zhang & Da-Chao Lin
North China Institute of Science and Technology, Architecture Engineering College, Yanjiao, Beijing, China

Jing An
North China Institute of Science and Technology, Telecommunications College, Yanjiao, Beijing, China

ABSTRACT: Based on the research of existing gas emission methods and technique, this paper firstly points out the problems of present prediction ways for gas emission. Takes the coalface gas emission of a coal seam as example, collects its gas emission measured data. On this basis, the prediction model of gas emission for coal beds based on the EMD and BP-ANN set up, the intrinsic mode functions, that is, IMF components, are obtained by the EMD analysis of the historical recording dada of gas emission, and after the prediction of each intrinsic mode is carried out by the extrapolation of its regression function determined by the BP-ANN, then the prediction result of gas emission is derived through the reconstruction summing all prediction results corresponding to different intrinsic modes. From an application example related to the monitoring data it can be seen that the introduction of EMD method into the theoretical modeling to predict the gas emission from the coalface obviously improves the accuracy in comparison with the conventional BP-ANN method, to have the prediction results agreement with the monitoring data. The study is to provide important scientific basis and decision support for more reliably and accurately gas disaster warning.

1 INSTRUCTIONS

At present, mine gas is the major risks affecting coal mine production safety in China, the safety problems caused by the gas accounted for over 80% of coal mine production safety accidents, and its casualties account for 90% of all serious accidents' casualties (Li & Jing 2007), Especially the gas explosion accidents, which have caused worst human and economic losses. From 2004 to 2009, various national coal mine accidents caused more than 10 people died approximately 225 cases, 5280 people deaths, of which including 147 gas accidents, 3,667 people deaths, accounting for 65.3% and 69.5% respectively. After restoration efforts, the industry in recent years, coal mine production safety situation in China is a little better. But the coal mine production safety situation is still grim, the total accidents is still too large, serious accidents have occurred from time to time. Based on the statistical data of the state production safety supervision and Management Bureau in 2010 and other statistical data, in 2010 China's coal mine gas accident occurred 135 cases, killed 593 people (Chen & Zhao 2012). Therefore, the coal mine gas disaster is one of the key factors to the coal industry production safety in china. Research shows that, in order to solve the gas disaster problem fundamentally, accurate prediction of mine gas emission is the key[1].

In recent years, the gas emission forecasting technology has been gained more and more attention in the world's coal-producing countries, they put a lot of human and financial resources to conduct technical researching, have obtained many reference experience and research results.

Such as British established the Airey method considering the time and mining conditions for the influencing factors, Germany is presented the Winter method to dynamic forecast the mining working face gas with time series, and the Pittsburgh mining research institute of United States etc.

The gas emission prediction study in China's coal mine started relatively late, for example, Qu Fang proposed the fully mechanized workface gas emission prediction method based on the initial velocity of gas emission (Qu et al. 2004); Yuan Dong-sheng applied three-dimensional grey trend surface analysis method to the prediction of gas emission (Yuan & Hao 2004); Xia Hong-chun proposed the prediction method of deep mine area gas

[1] Sponsors: The basic research costs of national universities: JCB2013B08

emission based on least square method (Xia et al. 2002), which established a linear regression equation between the working surface mining depth and the relative gas emission by using the method, and using the equation to predict gas emission from the deep region; Chen Fu-yong applied numerical analysis to gas emission prediction for mine untapped area (Chen 2004), which made fitting analysis on the existing discrete data of gas emission and depth by using the numerical analysis method, to find the approximate function between the gas emission amount and the mining depth, thus realizing the untapped area gas Emission prediction; Wu Ai-you introduced the grey theory into the gas emission prediction and established the prediction mode (Wu et al. 2005); Zhao Chao-yi applied the genetic programming to coalface gas Emission prediction (Zhao & Yuan 1999), to establish the prediction model of coal face gas emission. However, the above method is essentially pay more attention to the fitting effect of gas emission data that has occurred, applies only to the critical gas explosion forecasting, also cannot meet the early warning requirements (Hu 2001).

In addition to statistical mathematics, theory of gray system modeling method, the application of nonlinear theory and artificial intelligence method are also greatly enriched the theory means of gas emission prediction and gas time forecast based on observation data. For example, Liu Xin-xi put forward a method to predict the mine gas emission amount based on BP artificial neural network (Liu & Wang 2002); Xue Peng-qian considered the problems of slow convergence speed, easily falls into local optimization when use the traditional neural network method to solve nonlinear problems, proposed a new wavelet neural network method for gas emission prediction, which not only made full use of the time-frequency localization properties of wavelet transform, but also combined with neural networks self-learning ability, and established the prediction model (Xue et al. 2006); Wu Cai-fang combined neural network and genetic algorithm organically, with the neural network theory as the foundation, using genetic algorithm to optimize the hidden layer neurons and the number of connection weights in the network, established the gas content prediction model (Wu & Zeng 2003). But the above approaches has at least a fatal defects in the following two aspects, one is the excessive dependence on the monitoring data that can't be taken into account the real mechanism link between them and their real physical process, two is no observational existing data for a new mine, so there is no guidance to its design on the whole.

Obviously, the limited observational data alone does not fully reproduce all the characteristics of the problem. More importantly, for a time series, we can use only the time variable, it shows the features contained linking the clue is not clear. However, the literature studies provide some inspiration (Wang 1999), which can seek the changing characteristic of gas emission under different time scales by signal decomposition, considering different gas emission control mechanism should have different time scale effects, the link between the gas emission variations and its intrinsic physical mechanism is expected to explore through the difference of the time scales. However, the wavelet transform of digital signal analysis techniques are based on a pre-selected basis functions on the characteristics, does not meet the physical mechanism varies with time.

On the other hand, for its good adaptive decomposition effect, the empirical mode decomposition (EMD) method proposed by Huang et al in 1998 provides a possible approach to solve this problem (Huang et al. 1998). Based on the EMD method, it can make directly decomposed to the observed gas emission data, the approximately orthogonal intrinsic mode function (IMF) can be obtained, whole emission observations is the sum of these IMF components.

At the same time, considering the advantages and shortages of neural network in recent years in the treatment of prediction problems (Liu & Wang 2002, Zhu et al. 2007), this paper presents a new prediction method for coalface gas emission based on the EMD and BP-ANN. By using the gas emission historical data, obtains its intrinsic mode functions (namely IMF component) through the EMD decomposition, then corresponding respectively to each intrinsic mode make forecast by using the function fitting method of ANN, on this basis, different intrinsic mode prediction results were synthesized, reconstructed and synthesized, thus obtaining the theoretical prediction results for gas emission. Examples analysis of monitoring results show, compared with the conventional neural network method and other forecasting methods, the EMD method is greatly improving the prediction accuracy, whose prediction results are very consistent with the actual monitoring data.

2 THE DYNAMIC PREDICTION MODEL ESTABLISHMENT OF EMD-ANN

2.1 *The basic principle of EMD*

The intrinsic mode extraction of gas emission monitoring value can be achieve through the EMD method, although the EMD method has not been strictly theoretical proved, however, it has

got good results in many applications, also found some physical contact between it and some physical mechanisms.

According to Huang et al, intrinsic mode components should meet the following two conditions (Huang et al. 1998):

1. In the whole component signals, the number of zeros and poles are equal or different at most one;
2. For any point in the signal, the envelope determined by the local maximum point and the envelope determined by the local minimum point, whose average value is zero.

The time series signal of monitoring data is decomposed into several IMF and EMD steps as follows. Firstly, to identify all extreme points for the monitoring data signals x (t), then, the upper envelope $e_{sup}(t)$ and the lower envelope $e_{inf}(t)$ of $x(t)$ are respectively fitted by using all the maxima points and minima points, and they meet the following relationship:

$$e_{inf}(t) \le x(t) \le e_{sup}(t) \tag{1}$$

Set the average value of $e_{sup}(t)$ and $e_{inf}(t)$ with $m(t)$, there is:

$$m(t) = [e_{sup}(t) + e_{inf}(t)]/2 \tag{2}$$

Let the $x(t)$ minus the $m(t)$,

$$c(t) = x(t) - m(t) \tag{3}$$

The $c(t)$ to see as a new $x(t)$, repeat the above process, until the resulting $c(t)$ and the last calculated $c(t)$ satisfy the given consistency determination conditions, it can filter out the first order IMF component $c_1(t)$ from the original time series signal. At the same time, there is:

$$m_1(t) = x(t) - c_1(t) \tag{4}$$

Set $m_1(t)$ as a new $x(t)$, using the same method that can filter out the other IMF component sequentially.

At last, $x(t)$ can be expressed as

$$x(t) = \sum_{k=1}^{n} c_k(t) + m_n(t) \tag{5}$$

n is the number of decomposition, it is the number of IMF components determined by the monitoring signal features, namely the total number of intrinsic mode, $m_n(t)$ is the residual after decomposition.

Because of the time curves of gas emission is not very complex (He et al. 2008), so in strike the upper and lower envelope, the study used cubic spline interpolation. In addition, the data mirror extension method is applied to eliminate end effect (Lee et al. 2009).

2.2 *Forecasting model of BP neural network*

Artificial neural network (ANN) is a new subject produced in the late 1980s with rapid development, is an information processing system based on the imitation of human brain structure and function. At present, the ANN has been widely applied to all areas of our lives.

The typical BP neural network has three layers, namely: input layer, hidden layer and output layer, to achieve full connectivity between each layer, seen in figure 1. The detailed prediction process can refer to the literature[9].

By using the gas emission historical data, obtains its intrinsic mode functions (namely IMF component) through the EMD decomposition, then corresponding respectively to each intrinsic mode make forecast by using the function fitting method of ANN, on this basis, different intrinsic mode prediction results can be synthesized and reconstructed, thus obtaining the theoretical prediction results for gas emission.

The prediction accuracy using average relative error (MRE) is:

$$MRE = \frac{1}{n}\sum_{i=1}^{n} \left| (y_i - \hat{y}_i) / y_i \right| \times 100\% \tag{6}$$

In the formula, y_i is the monitoring values, $\hat{y}_i$ is the predictive value.

3 EXAMPLE

Taking the coalface of Dongpang coal mine in Xingtai as an example, the mine is the most abundant coal resources in Xingtai mining area, whose annual production capacity about 1.8 million tons.

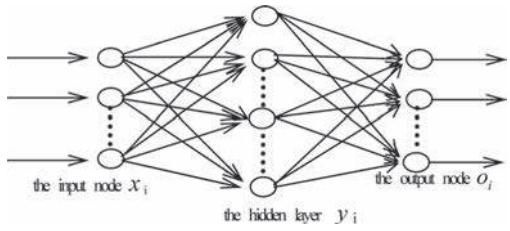

Figure 1. The typical BP-ANN model.

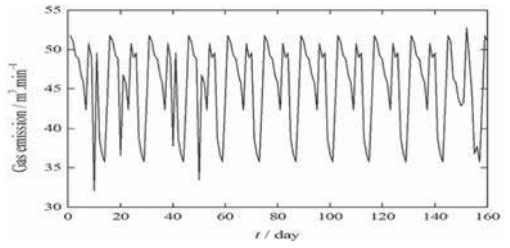

Figure 2. the monitoring results of coalface gas emission.

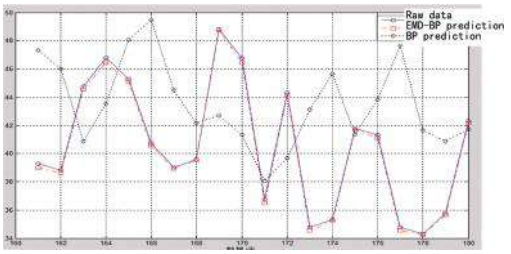

Figure 3. Comparison between measured and two predicted results.

The 6_{-2} coal seam is the main mining seam, integrated mining face in high gas zone. Select the top 160 gas observation data as the theoretical modeling sample data, as shown in Figure 2, the remaining 20 gas observation data as the test sample data, to make empirical study.

Six IMF components of the sample data are obtained through EMD analysis, therefore, the relevant mine gas emission in coal face changes over time contains total of six natural modes. Make predict to these six intrinsic modes separately through BP neural network, the prediction results from 161 day to 180 day are obtained after accumulative synthesis of each intrinsic mode prediction results as shown in Figure 3. It is not difficult to see, the prediction results based on EMD and BP-ANN are in good agreement with the actual test results, the prediction result of BP-ANN is clearly much worse. The average relative error is only 2.08%, while the latter is as high as 19.47%.

As can be seen, in the gas emission prediction modeling of coalface, when let the monitoring results as the modeling data, the gas emission laws in different time scales is difficult to fully revealed, to establish a theoretical model to predict the effect is not ideal, the introduction of the intrinsic mode in some extent overcome this deficiency. Although the application of the above examples may not reflect the whole features of gas emission problem, but the prediction results in Figure 3 at least one side confirmed the good predictive ability of EMD and BP-ANN prediction modeling for coalface gas emission. In addition, the theoretical modeling and calculation process of this method is relatively simple, and without excessive pursuit of how to optimize and select calculation parameters and other details, showing good engineering application value.

4 ANALYSIS AND CONCLUSION

This study reviews the existing gas emission prediction technology, designs and proposes a new prediction model for gas emission based on EMD-BP ANN, and apply it to the forecasting process of mine gas emission. The results show that, the model is feasible and effective, and can be used to predict the gas emission dangerous for large-scale coal seam. By predicting that if the gas emission abnormal, we can take the following measures to control:

1. Strengthen geological exploration work, seriously and comprehensively analyze the geological conditions before the mining face production, use vibration shot release the gas in advance if necessary.
2. Strengthen the management of the ventilation system, to ensure that the system is reasonable and effective, the air is sufficient.
3. Strengthen safety monitoring system repair and management, ensuring normal operation of the system. All mining face must be required to install gas automatic alarm and cut-off device, wherein the abnormal gas zone in high gas area, to achieve "three special two locking."
4. Strengthen gas prediction. Check the gas concentration each shift on coal hole of all underground mining working face, to predict the gas changing trends of the coalface forward direction through gas concentration changes analysis, and to take effective preventive measures in advance.
5. Strengthen the maintenance and management of electromechanical equipment, and resolutely put an end to electrical equipment explosion and illegal operation phenomenon.

In actual mine engineering, because there are many factors influencing the gas emission, the characteristics of coal seams and geological characteristics vary, so how to scientific and comprehensively extract the various factors influencing gas emission, is a further research topic.

Electromagnetic method in detecting water hazards in coal mining face

Xianxin Shi & Yanwei Hou
Xi'an Research Institute of China Coal Technology and Engineering Group Corporation, Xi'an, Shaanxi, China

ABSTRACT: Water hazards in mining face are prone to cause inrush accidents and result in production interruption, even lead to underground water flooding, injuries or deaths. Pre-proved water hazards with known distributions in the mining face followed with effective water prevention measures taken are crucial for preventing or reducing flooding accidents and ensuring safe and high-efficient coal production. Due to the sensitivity of Coal Mine Electromagnetic Method towards water-bearing body with low resistivity, this sensitivity plays a unique role in detecting water hazards in coal mining face. This Paper introduces the working principles and construction methods of Mine High-density Electrical Method, Voice Frequency Electric Perspective Technique and Mine Transient Electromagnetic Method applied for detecting water hazards in mining face; describes the application effects for the detections of water hazards on the floor in coal mine roadway, in Working Face and in Single Entry Mine Tunnel respectively. Focuses are rested on the methods, principles and effects of Voice Frequency Electric Perspective Technique and Mine Transient Electromagnetic Method for coal mine detection. Finite Element Method (FEM) is used for simulating the underground potential of point electric source and the response of abnormal body with low resistivity both in homogeneous half-space in purpose to explain the basic theory of Electric Perspective. The application cases show that Coal Mine Electromagnetic Method is sensitive to the water-bearing body with low resistivity, possesses higher resolution capability for water-bearing geologic body when closely to target detection layer or the geological body, is one of efficient method to detecting water hazards in working face.

1 INTRODUCTION

Hydro-geological conditions for coal mines in China are complicate with severe water hazards. Coal mine water hazard, the second disaster, second only to gas explosion accident, ranks the first when counting the economic losses comparing with other disasters.

Water inrush accidents for coal mines mainly occur in mining face, especially in heading face. According to the statistics made by the Accident Investigation Department of State Administration of Coal Mine Safety, there are altogether 24 water hazard accidents occurred for coal mines nationwide with the death toll up to 122; within which, 8 are of less severity: 6 accidents happened in heading face, 1 in mining face; for 5 severe accidents, 3 in heading face and 2 in mining face. As a result, making studies on detecting water hazards in mining face, taking precise positioning theories and methods, checking out water-bearing position, water-bearing geological body and potential water flowing channel in mining face and evaluating the influence taken by water-bearing body towards mining are of great importance, and all of these are the crucial measures for preventing and solving water accidents for coal mines.

Electromagnetic methods adopted to detect hydrogeological condition of coal mines can be classified into two main types, ground electromagnetic method and mine electromagnetic method. Taking forecasting of water hazard in coal mines for example, our country has formed an integrated geophysical prospecting technology system in the long-term production and practice, giving priority to the mine electrical exploration and taking technologies like mine high-resolution earthquake exploration, radio-wave penetration, down-hole microgravimetry, radioassay and infrared temperature measurement as auxiliaries, all of which provide effective technical measures for safe production of coal mines and play an unique role in water prevention and control of coal mines (Chu Shaoliang 1996, Yue Jianhua & Liu Shucai 2000). At present, the commonly-used mine electrical exploration methods include mine DC electrical method, electric transmission tomography, mine transient electromagnetic method and etc., which are mainly applied to hydrogeological detection on supply source of mine water-gushing, insidious water-conducting passage, fissure zone, thickness of aquifuge, water-bearing formations in front of heading face of the roadway and etc., as well as detection on small water-bearing formations

and karst collapse columns in the coal face (Liu Qingwen 2001, Wang Guohua et al 2003, Guo Chun et al 2006).

2 MINE HIGH-DENSITY RESISTIVITY METHOD

2.1 *Detection principle, method and technology*

Mine high-density resistivity method is a combined method with multi-device and multi-electrode-distance, integrating electrical section method and electrical depth-measuring method into one. For the application of the mine high-density resistivity method, it is only needed to once set dozens or hundreds of electrodes at measuring points with a certain distance from each other, whose density, usually 1–10 m, is much higher than that of normal mine DC electrical method. Figure 1 is distribution schematic diagram of measuring points of the high-density resistivity method. If the array distance of electrodes is "a", the measuring electrode distance is $x = n \cdot a$, in which $n = 1, 2, \ldots$ in sequence. Each electrode distance moves point by point from left to right according to the form of fixed device to finish the data acquisition of this electrode distance. For one electrode distance, the result is equivalent to that of the resistivity section method, while observation on different electrode distances at the same record point is equivalent to an electrical depth-measuring point. For the convenience of actual work and facilitating the realization of automatic measurement of apparent resistivity, Wenner array, Schlumberger array, dipole-dipole array and monopole–dipole array are always adopted by the high-density resistivity method system. Detecting depth of the resistivity method increases along with the increase of distance between power-supply electrodes C1C2 and when the isolation coefficient "n" increases in sequence, the electrode distance between C1C2 increases gradually, as well as its capability of response to deep underground medium. Measurement result of the high-density resistivity method is usually recorded at the midpoint of observing electrodes P1P2 and the point location of a depth of na.

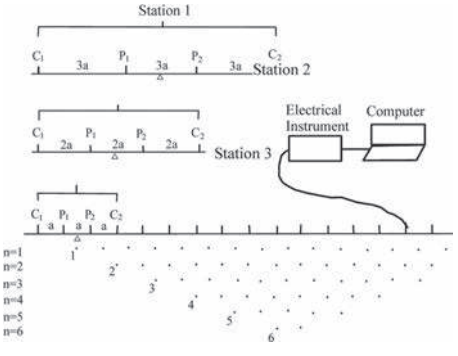

Figure 1. Schematic diagram of electrode array pattern and measuring point distribution of the mine high-density resistivity method.

Compared with normal mine electrical depth-measuring method and mine electrical section method, the mine high-density resistivity method has features like high efficiency in construction and abundant information acquired. It can use measurement results of different device forms to calculate different ratio parameters and show the abnormal information, and also be capable to suppress inference and decompose compound anomaly to a certain degree. Due to its outstanding effect, it becomes one of the ideal methods for mine geophysical prospecting

2.2 *Application effect*

The following is the introduction of detection condition of hidden trouble of water gushing from the floor in the excavation roadway of Coal Face 1116 of Shaanxi Xinghuo Coal Industry Co., Ltd., adopting the mine high-density resistivity method. The Coal Face 1116, located in the south wing of Xinghuo Mine Field. The mining coal seam is 11# and its thickness is about 4.69 m and the average angle of inclination is 3.5°. Roof of the excavation roadway of the coal face is sandy mudstone, mudstone and siltite; and the floor is mudstone with Ordovician limestone below. Task of this detection is to detect the water-conducting formation of fracture zone, fissure development zone and etc. and the scope of water-rich area 80 m below the floor of the excavation roadway of Coal Face 1116, in order to provide basis for design of water prevention, control scheme, arrangement and implementation of the water prevention and control engineering to ensure the safe mining on the coal face.

Figure 2 and Figure 3 are the floor detection results respectively of headentry and tailentry of Coal Face 1116 by adopting the mine high-density resistivity method.

As is shown in Figure 2, the resistivity on this section changes greatly both longitudinally and transversely, indicating the relatively complicated geoelectric structure. In the diagram, change from

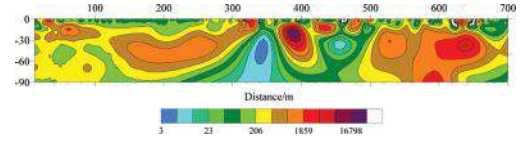

Figure 2. Headentry resistivity at coal face 1116 that detected by high-density resistivity method-depth section.

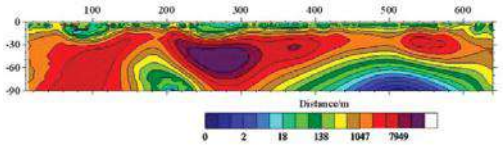

Figure 3. Tailentry resistivity at coal face 1116 that detected by high-density resistivity method-depth section.

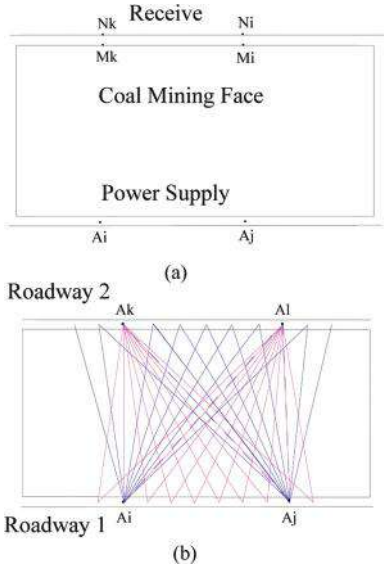
blue to red represents the change of apparent resistivity from low to high. There are mainly two places where the apparent resistivity is lower than the wall rock in Figure 2, and they are shown as blue low-resistivity abnormal zones.

Based on the analysis of apparent resistivity value, we take the abnormal segment with its apparent resistivity lower than 30Ω.m as low resistivity segment, and regard it as possible hidden trouble of water gushing. Therefore, two low resistivity anomalies are outlined according to the above principle. One of which with 332–355 m as its horizontal extent and 50 m approximately as its central buried depth on section; the other one with 440–470 m as its horizontal extent and 40 m as its central buried depth. The explanation on low resistivity in Figure 3 can be made in the same way: 490–520 m as horizontal extent and 85 m as its central buried depth. Thereby, drilling hole layout and verification can be adopted by mining party when abscissa of haulage way is at 510 m and abscissa of air-return way is at 345 m respectively. As the maximum water discharge is 67 m^3/h and 45.7 m^3/h respectively when drilling enters into the abnormal zone, grouting shall be taken to bottom plate immediately to reinforce.

The detection achievements of mine high-density resistivity method provides scientific basis for design of water prevention, control scheme, arrangement and implementation of the water prevention and control engineering at Coal Face 1116. Relying on these results, the coal floor of abnormal zones of this mine have been processed by drilled grouting; after the transformation of grouting, coal mined safely from this coal face has reached 210 thousand tons.

3 ELECTRIC TRANSMISSION TOMOGRAPHY

The principle of the electric transmission tomography is similar to that of mine radio-wave penetration method and the difference is that the electric transmission tomography adopts stable and constant current field. Actual construction layout is one-supply and multi-collection, forming a densely-covered bidirectional sector observation system



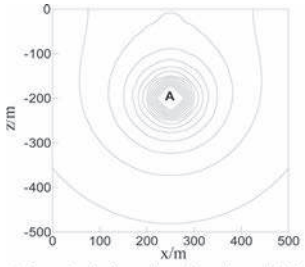


Figure 4. Layout diagram of down-hole electric transmission measurement.

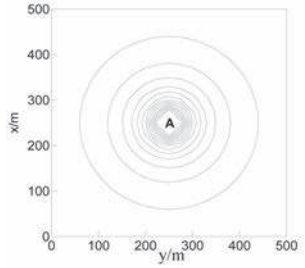
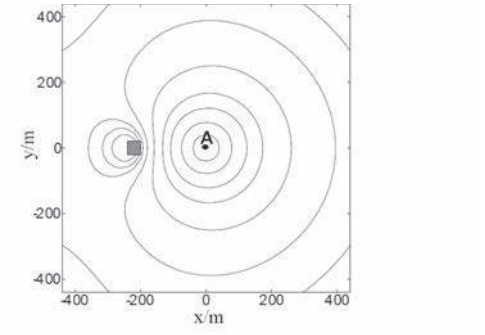
(Figure 4), to research the distribution rules of electric fields in coal faces between two roadways as well as in the wall rock.



3.1 *Basic principle of detection*

Its basic principle of detection can be interpreted by 3-D finite element simulation (Zhou Xixiang & Zhong Benshan 1986). Suppose the earth resistivity is 100Ω.m, the point power supply is placed 200 m deep underground, and equipotential diagrams of longitudinal section (Figure 5-a) and transverse section (Figure 5-b) of the stable and constant current fields generated by the underground point current source A can be provided, then we can find that on the transverse section of point power supply, the equipotential lines are a group of concentric circles. When a low-resistivity abnormal body of 10Ω.m resistivity is placed at the position with horizontal coordinates of X = –200 m and Y = 0 m and 60 m below the point power supply A, the anomaly response calculated is shown in Figure 6. Influence of the abnormal body on spherical-shell equipotential lines is that changes of equipotential lines around the abnormal body are greatest and the farther the equipotential lines are from the abnormal body, the less the changes are. Generally speaking, when the spherical-shell equipotential lines are near to the abnormal body, they will show the low-resistivity characteristic (attracting current) of the latter.

It is indicated by three main diagrams of the 3-D finite element simulation shown above that



(a) Longitudinal section of equipotential lines of point source 200m deep underground (earth resistivity: 100Ω.m)

(b) Transverse section of equipotential lines of point source 200m deep underground(earth resistivity: 100Ω.m z=-200m)

Figure 5. Longitudinal and transverse sections of underground point source

Earth resistivity: 100Ωm; Abnormal body: 40m×40m×40m, 200m below the power supply A; Resistivity: 10 Ω.m

Figure 6. Abnormal body response on the plane 200 m deep underground.

the potential lines of relatively deep down-hole power supply are basically free from influence of the semi-space; the abnormal body below the source influences distribution of plane potential lines of the source; according to the principle of electrical method, electrical difference between the abnormal body and wall rock, scale of the abnormal body and distance between the abnormal body and source will all influence the amplitude of anomaly, which is the basic principle of using monopole-dipole device to carry out down-hole electric transmission.

3.2 *Application example*

In the following part, results of water gushing detection by electric transmission tomography at Coal Face 1031 in Taoyuan Coal Mine of Anhui Huaibei Mining Group are introduced.

3.2.1 *Geological profile*

Coal Face 1031 in Taoyuan Coal Mine mines coal seam No. 10, with burial depth is 327–445 m. Strata in roof and floor of coal seam No. 10 usually are siltstone, fine sandstone or interbedding of siltstone and packsand, which water-bearing feature is weak; about 58 m below the floor of coal seam No.10, there is a stratum of Taiyuan formation limestone (limestone No. 1) of a thickness of 2–3 m, which is one of the major aquifers of mine.

The Taoyuan formation limestone and sandstone in roof and floor of the coal seam are all pressure-bearing aquifers, containing extremely inhomogeneous water; their water-bearing feature is mainly subject to karst, hole and fissure development degree. If partial fissure formation or water-bearing formation of the stratum is within high degree scope of water-conducting fissure development, they will extremely possible to threaten the safe mining at coal faces, and even lead to water trouble accidents. Therefore, it is required to find out hydrogeological conditions in the coal face in advance, in order to provide basis for water prevention and control before mining and implementation of appropriate technical measures during mining.

3.2.2 *Detection effect*

Figure 7 is the achievement diagram of electric transmission detection on water-bearing feature of strata near to segment below the floor of Coal Face 1031 by a certain depth. As is shown in the diagram, values of apparent electric conductivities of strata in the segment are changing within 0.16–8.2 S/m, with an average of 1.5 S/m. According to the general rule, that is, if the electric conductivity is high, the water-bearing feature will be good, we can come to the conclusion that the water-bearing abnormal zones in the coal face are mainly in the inner segment (southern segment), which shall be treated with water prevention & control measures during mining at the coal face.

4 MINE TRANSIENT ELECTROMAGNETIC METHOD

4.1 *Method introduction*

The mine transient electromagnetic method is very sensitive to water-bearing low-resistivity bodies

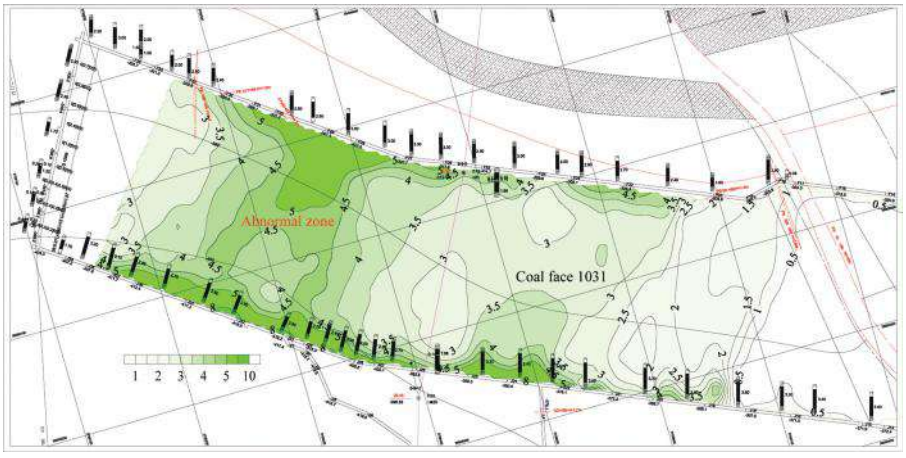


Figure 7. Plane figure of apparent electric conductivity by electric transmission tomography in the coal seam floor of coal face 1031.

and of fine directional property (orientational property); as a result, it can be applied to downhole omnibearing detection (not only available in front of heading end, but also for detection of lateral wall of roadway and roof, floor of coal seam and etc.); In addition, its advantages like long detecting distance and quick construction create a bright prospect for its application in detecting hidden trouble of water gushing at coal face.

4.2 *Calculation of apparent resistivity by the mine transient electromagnetic method*

The apparent resistivity of the mine transient electromagnetic method is a comprehensive reflection of electric conductivity of the whole-space stratum, and its formula is (Jiang Bangyuan. 1998):

$$\rho_\tau = C\frac{\mu_0}{4\pi t}\left[\frac{2\mu_0 SN}{5t(V/I)}\right]^{\frac{2}{3}} \tag{1}$$

In the formula, C is whole-space response coefficient; S is area of receiving coil; N is the number of coil windings of; t is attenuation time of the secondary field; and V/I is normalized induced voltage value.

4.3 *Conversion between time and depth by the mine transient electromagnetic method*

According to the fact that the underground induced current is distributed like rings and the "smoke ring effect" theory of electromagnetic field transmission, the vertical spreading speed vs and depth D of the electromagnetic field under random distribution condition of conductive medium are:

$$v_s = \alpha\frac{\sqrt{\gamma}}{\sigma_i\mu a}\times\left\{C_1+(C_1^2+2)^{\frac{1}{2}}+\left[1+C_1\Big/(C_1^2+2)^{\frac{1}{2}}\right]\gamma C_2\right\} \tag{2}$$

$$D = v_s t_i \tag{3}$$

While C_1 and C_2 are determined by the following formula:

$$C_1(\gamma) = \frac{3\sqrt{\pi}}{4}\left[1-\frac{\gamma}{4}-\sum_{k=2}^{\infty}\frac{(2k-3)!!}{k!(k+1)!}\left(\frac{\gamma}{2}\right)^k\right] \tag{4}$$

$$C_2(\gamma) = \frac{3\sqrt{\pi}}{4}\sum_{k=0}^{\infty}\frac{(2k-1)!!}{k!(k+1)!}\left(\frac{\gamma}{2}\right)^k \tag{5}$$

In the formula, $\gamma = \sigma_i\mu\alpha^2/4t_i$; σ_i is apparent resistivity corresponding to time t_i; α is whole-space response coefficient; a is area of transmitting loop; τ is time constant; and $\mu \approx \mu_0 = 4\pi \times 10^{-7}$ H/m.

According to the apparent resistivity-time curve actually measured, the apparent resistivity-depth curve can be acquired through the conversion by (2) and (3), thereby the corresponding relation between electrical distribution and depth of the conductive medium can be determined.

4.4 *Application example*

4.4.1 *Geological profile*

Coal-bearing series in this area is typical North-China type Permo-Carboniferous system, coal

series stratum overlaid by Jurassic system, tertiary system and quaternary system. Basic formation of the mine field is a uniclinal structure; the direction of strata is 300–330°; inclined direction is 210–240° and the angle of inclination is 12–30°.

4.4.2 *Field working method, technology and working parameters*

In view of the field working conditions, device of coincident loops is used to measure; additionally, method test has been implemented according to actual field conditions in order to increase signal-to-noise ratio to the largest extent. The final working parameters selected are as follows: transmitting wire frame: 1.3 m × 1.3 m (10 windings in total); receiving wire frame: 1.1 m × 1.1 m (20 windings in total); emission current: 20 A; delay time of sampling: 20 ms; superposition times: 256 times.

4.4.3 *Detection result*

3-D all-wave processing and analysis on data acquired through the measurement shall be carried out, including wave filtering, smoothing, forward calculation and inversion; especially aiming at influences of metal brackets, rails and etc. in the roadway on the distribution of transient electromagnetic field, simulation should be done by finite-difference time-domain method to eliminate them; anomaly of low-resistivity geological body to be detected should be given prominence to, and resistivity section diagrams with the processing results should be drawn; then conclusions and interpretations should be given according to the spatial changing conditions of resisitivities reflected by the section diagrams.

Figure 8 is the vertical section figure of pilot detection in blind roadway by the down-hole transient electromagnetic method. As is shown in the diagram, there is an obvious low-resistivity abnormal zone about 275–320 m in front of the excavation face, and the center is at 310 m. After analyzing based on the geological condition, we deduce that the anomaly is reflection of the fissure zone of water-bearing formation. In the process of subsequent roadway excavation, water-bearing fissure zone is found at 282–317 m, whose amount of water gushing is 60 m^3/h. Due to the water detection & drainage adopted by the mine, safety of the excavation construction is ensured. Thereby the detection result of mine transient electromagnetic method is verified.

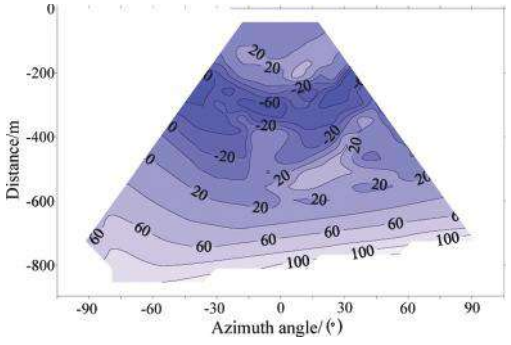

Figure 8. Resistivity section diagram of pilot detection in blind roadway of coal mine by the mine transient electromagnetic method.

5 CONCLUSION

Based on electrical differences between rocks, the electromagnetic method exploration is the main method for mine geophysical prospecting. Because of its sensitivity to water-bearing low-resistivity bodies, it shows a strong superiority in aspects of solving mine structures related to water and evaluating the water-bearing property. It has been proven by practice that the mine electromagnetic method is simple in construction, fast and economic, is an effective method for detecting hidden trouble of water gushing from the coal face and can provide reliable and correct basis for design of water prevention and control scheme for the coal face, as well as layout and implementation of water prevention and control project; thereby it plays an unique role in water prevention and control work of the coal mine and is very significant for ensuring the safe mining at the coal face.

ABSTRACT: After studying domestic and foreign related literatures, the prediction methods of existing water inflow in mines were summarized and analyzed in this study from two aspects, which are distributed-parameter method and lumped parameter approximation. Simultaneously, taking the Xinwen mining area as an example, numerical method, analysis method and analogue method were used to evaluate the water inflow in mines. Moreover, the characteristics and applicability of prediction methods were evaluated compared with the measured data. The evaluation results showed that: when the hydrogeology information file is enough in studied area, the numerical method can be used to predict water inflow in mines. When the research materials is not enough, the numerical method can be used to predict, meanwhile the analytical method need to be used as a comparison at the same time. For the newly-built mine, when the hydrogeology parameter is insufficient, the hydrogeology analogue method can be used to predict the water inflow. This study has certain guidance on choosing prediction methods at the analogous conditions in mine flow.

1 INTRODUCTION

How to accurately predict the water inflow in mines is an important issue during coal mining process, and that's also what the experts try to solve at home and abroad. Although many scholars have done a lot of work from different aspects and use different methods (Chen & Liu 2009) over the past few years. However, there still exist large errors between the predicted data and the measured data, and the biggest one can be more than ten times. The reasons causing the errors of prediction water inflow in mines can be mainly summarized in the following three aspects: failure to identify hydrogeological conditions, the selected hydrogeology parameter lacking represent activeness, improperly choosing the mathematical model (Dong 1995). Therefore, appropriately choosing the method of prediction water inflow in mines is an important way to reduce the errors. In this study, Xinwen mining area is chosen as study object. Meanwhile, the results of different prediction methods are analysed for water inflow in mines. Taking the recent actual measured data as a comparison, the applicability of the prediction water inflow is evaluated in mines under the areas condition.

2 OVERVIEW ON PREDICTION METHODS

Domestic and foreign scholars have done a lot of researches on prediction water inflow in mines, and summed up various prediction methods by practice. One is distributed parameter method, and the other is lumped parameter method (Du & Deng 2009). The most typical ones are: numerical method (Ma & Li 2011), analytical method (Song & Yang 2009), neural network method (Wen 2009) water balance method (Wu 2009), and hydrogeological analogy method (Zhang & Xu 2012) Distributed parameter method is represented by partial differential equations. Lumped parameter method is represented by ordinary differential equations. Figure 1 shows the classification on methods of prediction water inflow in mines.

2.1 *Numerical method*

1. Principle and application conditions
   Numerical method is an approximate calculation method, which is developed with the appearance of electronic computer, and is widely used recently. Theoretically, it is a method of approximate solutions for solving partial differential equations. The practical application of

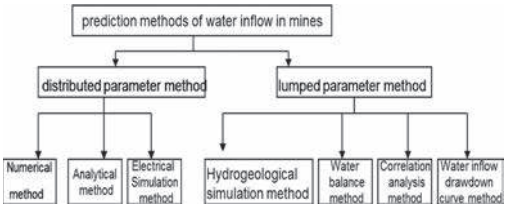

Figure 1. The classification on prediction methods of water inflow in mines.

this method can fully meet the precision need, and it also can solve many complex problems of water inflow in mines. What's more, numerical method can be very effective to the situation of simple hydrogeological conditions and simple aquifer system in the study areas.

2. Calculation method

Now the finite element method and the finite difference method are two commonly used numerical methods.

The finite element method: the finite element method is dividing the areas to be solved into finite units, and constructs the basis function in the unit. Then it constructs the shape function, and takes shape function as the approximate solution, finally uses Galerkin method or the principle of minimum potential energy to get the approximate value of the node.

The finite difference method: The finite difference method is replaced differential coefficient by difference quotient. So do the boundary conditions and initial conditions, turning the problem for determining solution to a algebraic equation set. Its essence is replacing the partial differential equation of groundwater movement by the corresponding differential equation approximately, and then solving the differential equation.

2.2 *Analytical method*

1. Principle and application conditions

The analytical method is one of the methods widely used in prediction of water inflow in mines and it is applicative to any roadway systems. The analytical method is based on the modeling requirement of analytical solution. Used the groundwater dynamics principle, and could be used to predict water inflow in mines after establishing an analytic formula of the ideal model.

2. Calculation method

The basic theorem of movement of the groundwater flow is Darcy's theorem. All the analytical formulas are based on or derived from it. The analytical method that is most commonly used is the well flow equation. It is basic formula can be divided into two categories: steady flow formulae (Dupuit Formula) and non-steady flow formula (Theis formula).

When using the analytical method, steady flow theory can solve two issues: predicting the totally water inflow in mines if maximum water drawdown of the mining level is known. The use of non-steady flow theory can solve the three problems: Predict water inflow in mines if the drawdown data and unwatering time is known. Predict the drainage time if the drawdown and drainage capacity is known. Predict the drawdown data of water level if the drainage capacity and unwatering time is known.

2.3 *BT neural network method*

1. Principle and application conditions

Artificial Neural Network (ANN) integrated the organization and function of applying engineering technology and computer. it is means to simulate the biological neural network. Artificial neural network is an artificial intelligent system which connects into a network through a large number of artificial neural cells that are similar with natural nervous system cells. The system realizes parallel distributed processing of knowledge.

2. Calculation method

BP network is divided into the input layer, hidden layer and output layer three layers and the full link of layers structure. Output layer can have multiple points (neurons). Hidden layer can be separated into multiple layers. If the number of hidden layer units is free to design, then uses three S-shaped, which can approach to any continuous function in arbitrary precision. Choose 3 layer networks (hidden layer is the first layer) will not affect the accuracy of the network, but also can improve the speed of the network.

2.4 *Water balance method*

1. Principle and application conditions

The water balance method is based on the principle of water balance, to find out the relationship between income and expenditure parts on water balance when mining the mine. It is applicative to the water-filled deposit of the non-seepage groundwater movement and simple water-equilibrium conditions. Therefore, find out the groundwater recharge and discharge conditions in the mining areas, research mine changes in the unwavering process, rationally confirm the balanced project as well as the data then can be combined the water balance calculation.

2. Calculation method

Through the study of the groundwater dynamics laws, establish the changing relationship between income and expenditure parts of groundwater in the mining area and in a certain period (equalization period), to establish a balanced equation to predict the water inflow of the mining area. Basic balance equation:

$$Q = Q_c + Q_y + Q_h + Q_{yh} + Q_r - (Q_c/ + Q_y/ + Q_h/ + Q_{zh}/ + Q_r/) - Q_{ch}$$

In the equation:

Q – The possible water inflow of the mining, m^3/d;

Q_c, Q_c/ – The underground runoff lateral inflows and the lateral leakage amount, m^3/d;

Q_y, Q_y/ – Leaky recharge and leaky excretion, m^3/d;

Q_h, Q_h/ – River recharge and drainage amount to the river, m^3/d;

Q_{yh}, Q_{zh}/ – Meteoric recharge and evaporation consumption, m^3/d;

Q_r, Q_r/ – Artificial recharge and manually pumping (row) amount outside the mine, m^3/d;

Q_{ch} – The amount of growth or consumption of aquifer storage capacity in unit time, m^3/d.

Storage capacity to a confined aquifer is the elasticity, diving watering layer is static reserves, for the steady state, this is 0.

2.5 *Hydrogeological simulation method*

1. Principle and application conditions

The hydrogeological simulation method is based on stable flow, uses the geological and hydrogeological conditions similarity, the drainage or gush material of the mine with the similar mining method to predict water inflow of the new mine. The application premise of this method is that the new mine has the similar conditions as the old one does, and the old mine should have a long-term observational data, to make sure the reliability of the mathematical expression between the water inflow and influencing factors, so it is just an approximate calculation method.

2. Calculation method

Hydrogeological simulation method mainly includes the rich water factor comparable method and the analogy method per water inflow.

① The rich water factor comparable method

It is based on the known mine rich water factor to prediction the neighboring new mine with the similar hydrogeological conditions and similar mining methods, namely:

$$Q = K_P P = \frac{Q_0}{P_0} P$$

In the equation:

Q – Water inflow of new designed mine (m3/a);

Q_0 – Water inflow of known old mine (m3/a);

P_0 – Production of known old mines (t/a);

P – Production of designed new mine (t/a)

② The analogy method of per water inflow

The physical meaning of per water inflow mine is the average actual water inflow in per unit drawdown and per mining area of the mine. If mine inflow water quantity (Q_0) is changing with the mining area (A_0) and water drawdown (S_0), the unit inflow water quantity (q_0) is

$$q_0 = \frac{Q_0}{F_0 S_0}$$

In the equation:

q_0 – Per water inflow of per area of production mine (m^3/H);

Q_0 – Total water inflow in mines (m^3/d);

F_0 – Roadway mining area of production mine (m^3);

S_0 – Water decreasing level of production mine (m);

According to the Per water inflow of per area of production mine, you can calculate total water inflow of deigned mine similar with other hydrogeological conditions:

$$Q_m = q \cdot F_m \cdot S_m$$

In the equation:

F_m – Designed mining area of designed mine (m^2)

S_m – Designed average water decreasing level of designed min (m)

3 PREDICTIONS AND ANALYSIS ON WATER INFLOW IN MINE

3.1 *Study areas*

Taking Longgu, Jiyang and Zhaoguan three mines of Xinwen Mining, as key study areas. And Longgu mine is located in Shandong Province, Heze county, main mining 3 # coal seam, with the complex structure. Jiyang mine is located in the north of the Yellow River, mining depth from-280 m to-750 m. Zhaoguan mine is located in Zhaoguan town, Dezhou Qihe County, and the earthquake

intensity is 6 degrees. And there are four principal coal seams in this court.

The main stratum of the study areas is Ordovician system, the black coal system and permian system, the Jurassic system Cretaceous system the Tertiary system and the Quaternary system. the coal system stratum is respectively the black coal system Benxi Group, the Taiyuan Group, and permian system Shanxi Group. The major aquifers in mines are: Quaternary conglomerate aquifer, Tertiary conglomerate aquifer, Permian Shanxi Group sandstone aquifer, Carboniferous Taiyuan Group limestone aquifer, Carboniferous limestone aquifer and Benxi Ordovician limestone aquifer.

Through studying the collections the materials of three mines in the area, its purpose is obtaining the hydrogeology parameter. The hydrogeology parameter directly affects the reliability and accuracy of the prediction data. Information of three mines is shown as Table 1.

3.2 *Different prediction methods of water inflow in mines*

Under the different situation, chooses LongGu, ZhaoGuan, and Jiyang mines as example. Using numerical method, analytical method and hydrogeology analogue method to predict the water inflow in mines. Analyzes errors of various prediction methods, to select the most suitable method to predict water inflow under similar conditions.

1. Numerical methods
   Since the mines have a wealth of information, and have a reasonably high hydrogeological parameters. The study takes the Longgu mining as an example, using numerical simulation method to research water inflow in mines. The results of water inflow in mines of major aquifer are shown in Table 2.

   Table 2 shows that the data of prediction of water inflow in mines by numerical method changes a little the error is smaller, compared with the actual data, So, the model satisfy the accuracy of prediction, can be used to predict water inflow.

   There are two reasons: ① Calculation method is not fully fit the actual groundwater flow movement. This is one of the main causes to the error. ② Lacks the understanding of hydrogeological conditions. Although the study area has accumulated a certain amount of research, still lacks observation materials and hydrogeological parameters of the groundwater.
2. Analytical method
   Using the analytical method to predict the water inflow of Longgu, Zhaoguan and Jiyang, three mines. The results are shown in Table 3.

   Table 3 show that there exist some errors between the prediction data and the actual data, especially for Longgu, Zhaoguan mines, which have a bigger errors by analytical method.

   There are three reasons: ① the complexity of boundary conditions and the aquifer medium, which will take water inflow errors. ② selecting the applicable formulas: the Dupuit equation is the steady flow of groundwater, but using the analytical method to predict water inflow in mines, the drawdown range from tens of meters to several hundred meters, is not a slowly varying flow. ③ errors from selecte impact radius, impact radius in mines is impossible symmetrical.
3. Hydrogeological simulation method
   Using hydrogeological simulation method to prediction water inflow of zhaozhuang and Jiyang mine, The prediction results are shown in Table 4.

Table 1. Collection information.

Mine	Information	Hydrogeological parameters accuracy
Longgu	Rich	Higher
Zhaoguan	General	General
Jiyang	Less	Lower

Table 2. The prediction results on water inflow in mines by numerical method.

Mine	Aquifer	Numerical simulation water inflow (m^3/h)	Actual water inflow (m^3/h)
Longgu	Shanxi3 sand	236	250
	Shanxi3 gray	845	720

Table 3. The prediction results of water inflow by analytical method.

Mine	Prediction aquifers	Water inflow (m^3/h)	Actual water inflow (m^3/h)
Longgu	Shanxi group 3 sand	343.4	250
	Shanxi group3 gray	834	720
Jiyang	10# aquifer roof	414.8	543
Zhaoguan	11# and 13#	2564.4	1669.2
	–415 m horizontal	343	245

Table 4. The prediction results of water inflow in mines by hydrogeological analogy method.

Mine	Water inflow Prediction (m^3/h)	Actual water inflow (m^3/h)	Formula expression
Zhaoguan	934		$Q_{set} = Q_{set} \times \sqrt{\frac{F_{real\text{-}time}}{F_{the}}} \times \sqrt{\frac{S_{real\text{-}time}}{S_{set}}}$ $F_{real\text{-}time}$ actual mining area $S_{real\text{-}time}$ levels of actual deep
Jiiyang	853	350	F_{the} anticipated mining area S_{set}, it is expected that water level down deep

Table 4 show that the hydrogeology analogue method has limited, can just be used for the approximate calculation.

There are two reasons: ① the hydrogeological conditions difference between existing materials of the water inflow in mines and the budgetary exploration areas. ② determining the analogy coefficient.

4 EVALUATION ON ERROR ANALYSIS AND APPLICATION

4.1 *Error analysis*

According to the all aspects of prediction the mine water inflow, the reason that may cause the prediction distortion of the mine water inflow can be summarized as follows:

1. Lacking the knowledge of hydrogeological conditions in mines, and non-identifying mine hydrogeological conditions
2. Improperly selecting the hydrogeological conceptual model. If the hydrogeological parameters data incorrectly or partition errors, boundary conditions or flow forms generalized improperly, will affect the accuracy of the results.
3. Mathematical model distortion. Usually, it is difficult to accurately describe the complex hydrogeological conditions and mining system with mathematic expressions. So to establish the mathematical model is hard, and slightly carelessness can make mathematical model distortion.
4. The well building engineering and the mining process in mine area are different from groundwater numerical simulation. Besides, the actual mining coal project unceasingly excavates according to the working area at time, while the numerical simulation treatment process does not simulate the groundwater by stages according to the actual coal mining project, instead it takes the mining time as the beginning stage of numerical simulation, and takes the finishing point of mining process as the end stage. Thus there exists some certain difference between prediction steps and actual mining engineering.
5. Influence on mining coal craft, well building practice and mining rate affected to predict water inflow in mines

4.2 *Evaluation on prediction methods and applicability of water inflow in mines*

1. Evaluation on applicability of numerical method
   Advantages: ① it can consider many factors, it has strong ability of adapting to boundary condition, is good at describing the non-isotropic and characteristics of aqueous medium, is easy to deal with the source and converge terms in control equation, it completely considers the non-linear problem about pressure-bearing turning to non-pressure in the process of pelting the deep sparse falling; ② It well solves various ground-water flow conditions under complex condition, and has the high precision; ③ The eological models by numerical method can clearly reflect the distribution information of each stratum.
   Disadvantages: ① modeling and operating work are heavy and time-consuming; the load of memory and computation is huge. ② It needs to revise water inflow in mines repeatedly, to make computation water levels of numerous controlled points drop to the designed requirements. ③ It needs the high systematic characteristics and accuracy of materials.
2. Evaluation on applicability of analytical methods
   Advantages: ① Analytical method in predicting water inflow in mines is simple and convenient; ② It is applicable to any type of roadway, as well as the water inflow in mines calculation of specialized unwatering drainage device.
   Disadvantages: By theoretical analysis and practice know that the method is not suitable for water inflow of large drawdown irregular mine calculations prediction.
3. Applicability evaluation of hydrogeological analogy methods
   Advantages: ① when hydrogeological conditions are quite simple, water inflow is not big and the mine of hydrogeology work degree is

low, it is available to use analogue method. ② When being used for the long-history production, we can forecast the water inflow of new expanded working area according to the actual draining water material of previous horizontal, or according to the draining water material of production working area, and the effect is good.

Disadvantages: ① When dynamic changes of influencing factors in mines water filling cannot be considered thoroughly, then we cannot use this method to forecast water inflow; ② When lacking of similarity under the geological and mining engineering conditions, it cannot be used too.

In summary, the analytical method operates simply, fast and economically, but the simplification of boundary and selection of parameter affect prediction accuracy. It is suitable for predicting water inflow under simple hydrogeological conditions, as well as simple boundary conditions; the numerical method is suitable for solving complex problems because of its quick computation, high prediction accuracy, simple computational method and economical, but it is an approximate estimation method and is suitable for the old mine with similar hydrogeological conditions and long-term water volume observation materials.

Therefore, in order to satisfy the accuracy and having the hydrogeology detailed material may use the numerical method to predict water inflow in mines. When lacking enough research area materials, may use the numerical method to predict water inflow by simulation, and simultaneously use the analytical method as comparison. The newly-built mine, when the hydrogeology parameter is insufficient, may use the hydrogeology analogue method to predict.

5 CONCLUSIONS

From the contents discussed above, the following conclusions can be draw: The prediction of water inflow in mines must follow three principles: finding out different conditions, using representative calculated parameters, and selecting the proper mathematical model. No matter which method is used to predict water inflow in mines, the amount of increment of mine groundwater must be calculated., Moreover, the rationality of calculating water inflow from the water balance must be considered in mines In order to obtain accurate water inflow data successfully, it is necessary to analyze hydrogeological conditions carefully to select the appropriate water inflow calculation methods. Different method has its special using conditions, and in the practical application, different methods. Then select quite accurate one by comparing and comprehensive analyzing water inflow in mines, only by this way can we accurately conform to the practical prediction of water inflow. We recommend that when predicting water inflow in mines, it is better use numerical simulation method, and then take other analogy extrapolating methods as supplement.

The application research of mine gas and the fire-reversed stove gas mixing

Guangxue Meng & Hong Guo
North China Institute of Science and Technology, Beijing, China

ABSTRACT: Currently on combustible gas safety studies mostly for single gas, and the study of multivariate mixed gases is less, only a handful of concentration explosive limits data reports[1,2]. This article proposes a application security research program about mixing two different sources, mine gas and fire-reversed stove gas which makes a detail about the theoretical analysis of the program' feasibility, the determination method of mixed gas explosion limit, and the process of using test unit to test determination. Finally, it introduces the safety measures, which should be taken in practical application.

1 INTRODUCTION

Mine gas is one of the main safety problems in coal production, which does great harm to coal mine safety production and people's life and property. Since 1980s, people pay more and more attentions to the comprehensive utilization of mine gas. At present, the widely used technique is pumping coal seam gas by gas drainage pumps, and compress it by gas compressor, and then used in industrial and civil fuel, or power generation, etc. According to this way, not only improve the safety of coal mine production, but also relieve the strain on energy, protect the environment, which achieves "to use for extraction, from extraction to promote safe" virtuous circle development of coal mines.

But the gas concentration and volume are greatly influenced by the resources of the mine and the geological conditions. If the gas pumping capacity reduction for some reason, it will affect the normal supply of gas users. The usually method is shutting down part of users, and shuts down all users gradually, causing a serious waste of original network and equipment.

In order to solve the problem, ensure the gas users of normal air supply, it puts forward under the condition of the mine gas reducing using a network of mine gas and the fire-reversed stove gas mixed with implementation plan. Not only has simple system, convenient management, less investment, more effect, but has the good social benefits and economic benefits as well. In order to use mixed gas safely, this article introduces the program's the feasibility analysis and safety testing.

2 FEASIBILITY RESEARCH

2.1 *Explosion limit of flammable gas*

Mine gas and fire-reversed stove gas are of high quality energy, they have their own explosion properties. After mixing them, their explosion characteristics will change.

Whether the combustible gas in the air will explode or not when it meets fire, which is associated with combustible gas concentration. This range is called explosion limit. We call the lowest concentration of combustible gas in the air explosion when it meets fire (in volume percent) the lower explosive limit; highest combustible gas concentration said the explosion limit. To avoid mixed gas exploding, we should find the gas explosive limits of each component.

2.2 *The algorithm of a single flammable gas explosion limit*

According to the requirement of number of oxygen atoms and combustion reaction, considering the oxygen content in air, we can determine the explosion limit of flammable gas:

$$X_{下} = \frac{100}{4.76(N-1)+1}\% \tag{1}$$

$$X_{下} = \frac{100}{4.76N+4}\% \tag{2}$$

where $X_{下}$ = The lowest limit of a single gas explosion; $X_{上}$ = The highest limit of a single gas

Table 1. The limit of a single flammable gas explosion.

Name	Molecular formula	Highest explosion	Lowest explosion
Hydrogen	H_2	75%	4%
Carbon monoxide	CO	74.2%	12.5%
Acetylene	C_2H_2	81%	2.2%
Ethylene	C_2H_4	32%	3.1%
Methane	CH_4	15%	5%
Ethane	C_2H_6	13%	2.9%
Propane	C_3H_8	9.5%	2.1%
Butane	C_4H_{10}	8.4%	1.9%
Pentane	C_5H_{12}	7.8%	1.4%

explosion; and N = The number of oxygen atoms when the combustible gas fully burning.

The above formulas calculate several single combustible gas explosion limit parameters are shown in Table 1.

2.3 *The calculation method of multiple gas explosion limit*

Firstly, we should make sure the proportion and form of the mixed gas. Secondly, we should benchmark the gas components. In other words, we convert it to pure gas composition, no air base composition and the gas composition. Thirdly, we should find out the explosion limit of the unit gas. Fourthly, we should calculate the explosion limit of the pure combustible gas, no air flammable gas. Fifthly, we should calculate the overall gas (including gas, inert gases (CO_2,N_2) and air) explosion limit in the air.

We can use the Lee Chatelle Formula to calculate the explosion limit of Compound and mixed steam.

2.3.1 *The calculation method of L*

No oxygen and inert (CO_2,N_2) of combustible gas explosion limit for L is:

$$L = \frac{100}{\sum_{i=1}^{n}(X_i / L_i)}\% \tag{3}$$

where X_i = An unit gas percentage (%); and L_i = An unit gas explosion limit.

2.3.2 *The calculation method of L_n*

L_n – The explosion limit of no oxygen containing inert gas (CO_2,N_2) is:

$$L_n = L \times \frac{(1 + X_N / (1 - X_N)) \times 100}{(100 + L \times X_N / (1 - X_N))}\% \tag{4}$$

where X_N = A inert gas percentage.

Table 2. The compositions of fire-reversed stove gas (%).

H_2	CO	CH_4	C_2H_6	CO_2	N_2	O_2
34.0	6.9	7.0	0.9	8.5	41.9	0.8

Table 3. The calculation results.

Mine gas accounted for the proportion of mixed gas (%)	0	20	40	60	80	100
The proportion of combustible gas (%)	95.4	82.3	69.2	56.2	43.1	30
The highest limit of flammable gas explosion (%)	62.01	50.35	40.21	30.56	22.58	15
The lowest limit of flammable gas explosion (%)	8.52	8.03	7.59	6.84	6.11	5
The difference of the flammable gas concentration exceeds the upper limit (%)	33.39	31.95	28.99	25.64	20.52	15.0

2.3.3 *The calculation method of L_N*

L_N – The explosion limit of oxygen containing inert gas (CO_2,N_2) is:

$$L_N = L_n(1 - X_{Air})\% \tag{5}$$

Where X_{Air} = The air percentage.

2.4 *The test data*

The volume fraction of methane in the mine gas is 30% and the air is 70%. The fire-reversed stove gas of compositions are shown in Table 2:

According to three different proportions, the original gas composition, no gas composition of air, no air and inert gas, we make hundreds of testing and calculating. We choose the calculation results of mine gas accounts for each of the gas sample components were 100%, 80%, 60%, 40%, 20%, 0.0%. The result is shown in Table 3. The analysis diagram as shown in Figure 1.

According to calculation results and analysis diagram, we can see when the explosion limit of combustible gas is between 15% and 20%, it is safe to use.

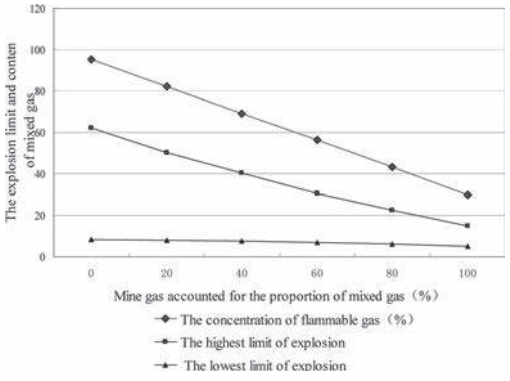
3 THE EXPLOSION LIMIT TEST

In addition to the theoretical analysis, we carry on the experiment of the explosion limit and the

actual measurement of the fire-reversed stove gas and mine gas in different proportion mixing.

3.1 *The explosion test method and test apparatus*

We usually use the propagation method to test explosion limit. The device is shown in Figure 2.



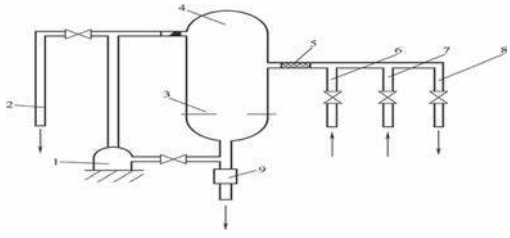


Figure 1. Result analysis.

Where 1-Circulating pump; 2-Pick up mercury manometer 3-Electrode; 4-Explosion tube; 5- Resistance fire net; 6-Pick up air; 7-Pick up samples; 8-Pick up vacuum pump; 9-Discharge air.

Figure 2. Explosion test apparatus.

The main components used 150 cm long, diameter of 7 cm hard glass tube explosion, tungsten rod ignition electrode diameter is 1.5 mm, pressure gauge, flow meter, circulating pump, etc.

Test principle: First of all, we should pump the air of the blast pipe, and then we should make it with a fixed pressure and temperature of a certain concentration of combustible gas and air. After mixing them averagely, we use the ignition electrode to light it, studying the communication situation of the fire. Flame propagation of low concentration or high concentration (gas volume percentage) is the lowest explosion limit and the highest explosion limit in a certain pressure and temperature.

3.2 *The test results*

The test condition: The initial temperature is $T_0 = 20 – 34$ °C; the initial pressure is $P_0 = 13.320 – 34.550$ Kpa. The reactor seals Mixture test results are shown in Table 4.

The results are shown that no matter what proportion to mix the mine gas and the stove gas, it will not explode, which is conformed to the analysis and calculation.

4 THE RESEARCH CONCLUSION AND SAFETY MEASURES IN PRACTICAL APPLICATION

4.1 *The research conclusion*

Through many calculations and tests, we can put forward it: with the stove's gas qualified (<0.8%) and mine gas (>30%) of different mixing proportion are outside the range of explosion, which is safe to use. After the trial is successful, we test three different gases, the coal gas, mine gas furnace and coking coal gas, which is also successful.

Table 4. The experimental results.

Constituent	O_2	CO_2	CO	H_2	CH_4	N_2	C_nH_m	Calorific value (KJ/M3)	The experimental results
Mine gas	15.5	0.85	/	/	28.6	55.1	/	10416.4	
Fire-reversed stove gas	0.40	7.30	34.05	48.82	3.03	6.15	0.25	11038.04	
Mine gas: Stove gas (1:2)	5.45	5.05	22.75	32.50	11.0	22.47	0.23	10886.77	Security
Mine gas: Stove gas (1:1)	8.00	4.07	17.06	24.40	15.85	30.41	0.22	10823.38	Security
Mine gas: Stove gas (2:1)	10.47	3.00	11.36	16.30	20.10	38.57	0.20	10739.23	Security
Mine gas: Stove gas (n:m)		…	…	…	….	…	…	…	Security
Air: Stove gas (1:2)	10.64	3.66	17.02	24.41	1.52	42.62	0.13	5524.61	Explosion

According to the result of three mixed gas test, mine gas concentration is above 30%, with qualified the fire-reversed stove gas and qualified coking coal gas by different mixing ratio, which is the same safe to use.

4.2 *The safety measures*

When using the gas and the fire-reversed stove gas mixing application we should take security measures.

1. We must guarantee the quality of produced gas, oxygen content is below 0.8%.
2. Mine gas concentration requires to more than 30%.
3. To send the fire-reversed stove gas and mine gas at the same time to arrival piping, together with sending the pressure to the gas holder.
4. Stove gas and mine gas should be analysis on a regular basis to ensure that the two gas conform reach the requirements of the specifications and standards, or stop gas holder.

5 CONCLUSION

According to the algorithm analysis and experiment, mixing the mine gas with two gas or even more, if we use it under a certain condition, we can use it safely. The technology has practical application in some coal enterprises.

Technology of controlling upper corner gas by pneumatic fan with vortex zone replacement

X.X. Chen, W.G. Jin, L. Gong & H.T. Li
Key Laboratory of Coal Mine Disaster Prevention and Control, Hebei, China
North China Institute of Science and Technology, Beijing, China

ABSTRACT: Because of high inclination angle and thick coal seam in fully mechanized coal face S204 in QiJiapomine, using U-type ventilation can easily result in gas overrun in upper corner. After the analysis of main source and accumulation causes of upper corner gas in fully mechanized coal face. The technology of managing upper corner gas by Pneumatic fan with vortex zone replacement is researched. The best installation location and technical parameters of pneumatic fan have been determined through numerical simulation methods, and the process parameters and the engineering implementation method of replacing upper corner are determined according to the pneumatic fan parameters. Application results show that after the technology has been carried out, gas concentration in upper corner decreased up to 61.78%, and the gas overrun has been effectively controlled, gas control effect is remarkable.

1 INTRODUCTION

Qi jiapo Mine of Baoji Qinyuan Coal Industry is a low gas mine, average relative gas emission is 4.6 m^3/t. Because of high inclination angle, upper corner in working face as leak points of goaf air flow can easily form gas accumulation zone if use U-type ventilation mode is used[1]. And upper corner gas would easily lead to gas overrun and bring great hidden danger to safety production if it is not properly controlled. How to effectively control the upper corner gas in working face is an urgent problem.

The main technologies of controlling upper corner gas in working face in the world scope are as follows: change the ventilation system, airflow dilution method, tail lane method, isostatic pressing method, fan pumping method, gas drainage method, etc[2,3,4]. These methods all play a certain effect in controlling upper corner gas. For instance, changing ventilation system could effect a radical cure for the gas accumulation in upper corner, but roadway maintenance and project cost is large. Airflow dilution is an economic method and simple to install, but the introduction of air volume is limited, ventilation resistance will increase, and operating environment would be narrowed. Tail lane method has a well effect for gas emission, but it is not suitable for the working face of easily spontaneous combustion because it will increase amount of engineering quantity, ventilation resistance and air leakage in goaf. Facilities of isostatic pressing method is installed in return airway and needed to be opened and closed frequently, a large number of gas would gush out once the ventilation system changed or the isostatic pressing facilities are destroyed. Fan pumping method can effectively solve gas overrun in the upper corner, but the fan is hard to install and operate, when the fan stops working, it will cause the problem of gas overrun. Gas drainage method is flexible and effective to control upper corner gas, but the drainage system must be installed, and the project quantities of installation is large. Qi Jiapo mine is a low gas mine and gas drainage system is not installed. After fully comparing the advantages and disadvantages of upper corner gas control technologies, the method of controlling upper corner gas by Pneumatic fan with vortex zone replacement in fully mechanized coal face S204 is researched, concentration of upper corner gas has been effectively controlled and safety production in working face has been guaranteed.

2 MAIN SOURCES AND ACCUMULATION ORIGIN OF UPPER CORNER GAS IN MECHANIZED COAL FACE S204

The fully mechanized coal face S204 is located in the south limb of Qi Jiapo mine, the average inclination angle of the coal seam is 15°, and the average thickness is 8.0 meters, the length of the lower roadway is 1560 meters and the upper roadway is 1500 meters, inclination length of working face is about 180 meters, U-type ventilation mode is used

in the working face. According to the field test data, it can found that along the inclination direction of the working face, the gas concentration changes little from the air inlet side to the middle of working face, but increases rapidly from the middle of working face to the upper corner, especially near the return air side in the range of 30 to 40 meters. This is because airflow takes goaf gas into the middle of working face where gas begins to accumulate. The monitoring point that perpendicular to the coal wall in the working face shows that the gas concentration in goaf side is much higher than that is found in coal wall side, which indicates that the goaf gas is the main headstream in working face.

Using U-type ventilation and under the air pressure between intake and return air way in working face, upper corner as the air leakage point in working face is the only way by which the emitted gas in goaf and airflow pass. Wind speed is very low in upper corner near coal wall and goaf side, and the wind current is located in vortex state. A large number of high concentration gas which emitted from goaf is difficult to enter into the main airflow due to vortex motion, and this motion leads to circulatory movement of high concentration gas and local gas accumulation near upper corner.

3 TECHNOLOGY OF CONTROLLING UPPER CORNER GAS BY PNEUMATICFAN

3.1 *Introduction of pneumatic fan function*

FQ series mine pneumatic fan is developed by China University of Mining and Technology, the working medium and the power of the motor are compressed air. Output shaft are installed at the both ends of fan, fan blade is installed in the front end and linen wind wheel driven by the fan airflow is installed in the back, and there has an incomplete circular air outlet in the linen wind wheel. Thus, blade and line wind wheel would be rotated by the fan when the fan is working, and a certain frequent and disturbed jet which can reach the range of 8 meters to 15 meters would be generated in a conical area, so it is suitable for blowing dead space of ventilation, especially for harmful gas accumulation in upper corner.

3.2 *Numerical simulation technical parameters of pneumatic fan for managing upper corner gas*

According to the mining conditions in working face S204, some parameters such as the average inclination of coal seam is 15°and the main airflow speed is 1.6 m/s, are input into FLUENT software. After the numerical simulation analysis for the effect of different location and technical parameter of pneumatic fan in upper corner field, the obtained data is shown in Figure1 to figure 4, it shows streamline distribution of flow field on the condition that the

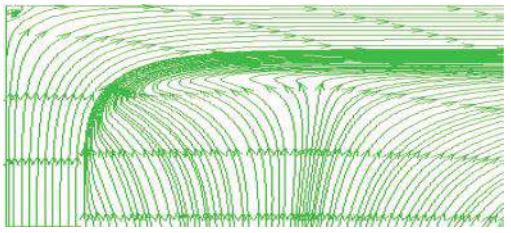

Figure 1. 4 meters away from the outer side wall in upper.

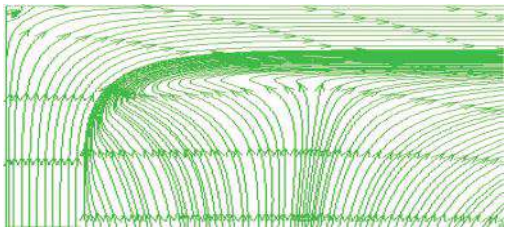

Figure 2. 5 meters away from the outer side wall in upper.

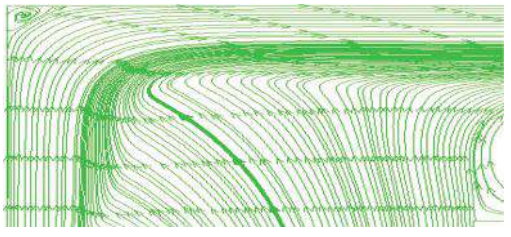

Figure 3. 7 meters away from the outer side wall in upper.

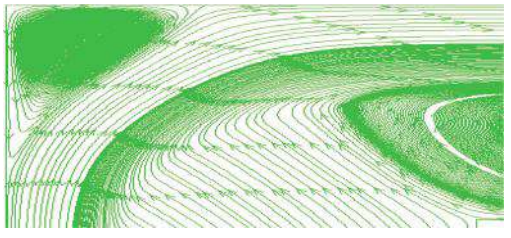

Figure 4. 9 meters away from the outer side wall in upper.

angle between airflow direction of pneumatic fan and main airflow direction is 0°, the vertical distance from the outer side wall in upper roadway to the pneumatic fan is 4 meters, 5 meters, 7 meters, 9 meters respectively. When the vertical distance mentioned above was 4 meters or 7 meters, there still existed a small vortex zone in upper corner; when the vertical distance was 5 meters, the vortex zone in upper corner was completely disappeared and maximum range appeared when the distance was 9 meters.

Figure 5 to 8 is the velocity vector diagram of upper corner field on the condition that the angle between airflow direction of pneumatic fan and main airflow direction is 0°, the vertical distance mentioned above is 5 meters, the exit velocity is 15 m/s, 20 m/s, 25 m/s, 30 m/s respectively. As is shown in the diagram, the exit velocity of pneumatic fan is different, the effects on the velocity vector in upper corner field is different. When the exit velocity of pneumatic fan is 15 m/s, 20 m/s, 30 m/s respectively, a small range of low velocity area is still existed in upper corner and the area would have disappeared when the exit velocity is 25 m/s.

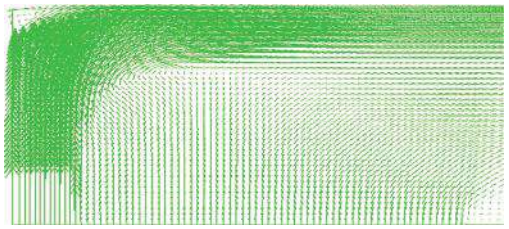

Figure 5. Exit velocity is 15 m/s.

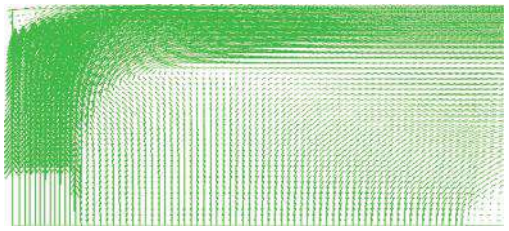

Figure 6. Exit velocity is 15 m/s.

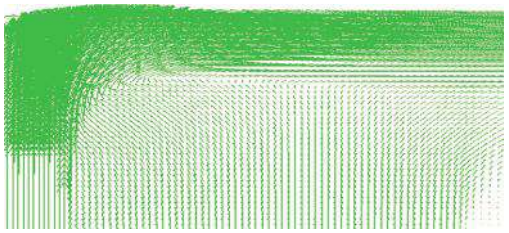

Figure 7. Exit velocity is 25 m/s.

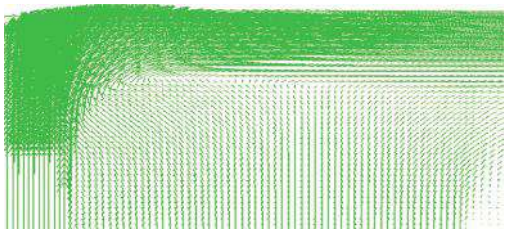

Figure 8. Exit velocity is 30 m/s.

Figure 9 to 11 is the streamline diagram of pneumatic fan under different exit airflow direction.

Though the analysis of numerical simulation mentioned above, the best installation parameters of pneumatic fan for eliminating the vortex zone in upper corner can be obtained. Namely, the vertical distance from the outer side in upper roadway to the pneumatic fan is 5 meters, the exit velocity of

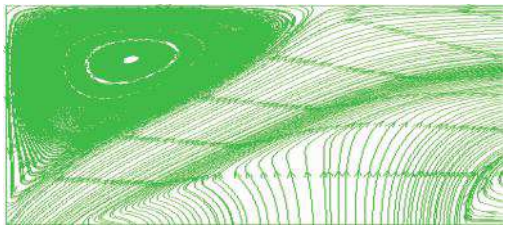

Figure 9. The angle between airflow direction of pneumatic fan and main airflow direction is 30°.

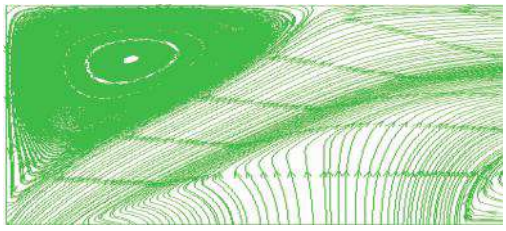

Figure 10. The angle between airflow direction of pneumatic fan and main airflow direction is 45°.

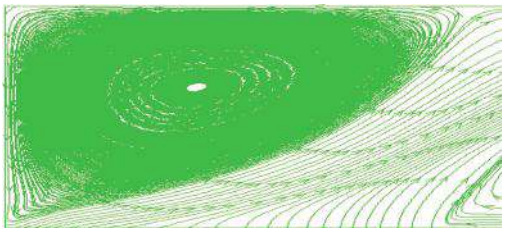

Figure 11. The angle between airflow direction of pneumatic fan and main airflow direction is 60°.

pneumatic fan is 25 m/s, the angle between airflow direction of pneumatic fan and main airflow direction is 0°.

4 CONTROLLING UPPER CORNER GAS BY VORTEX ZONE REPLACEMENT

Vortex zone replacement is used with pneumatic fan. This method uses some chemical material which is good at sealing and inflaming retarding(just like Hassfu) to replace the vortex zone generated in upper corner field, which can eliminate the space of upper corner gas. Meanwhile, in order to make upper corner gas flow with the main return air smoothly, the outer boundary of replacement in replacement area is made into an arc shape for reducing the wind resistance and facilitating the gas flow according to the morphological characteristics of out boundary in vortex zone.

The project of vortex zone replacement is shown in Figure 12. The technological parameters of replacement management is determined by the parameters of pneumatic fan, the details are as follows:1) The center angle corresponding to the arc AC is 60°, 2) The vertical distance of AB is 3.0 meters, 3) The horizontal distance of BC is 2.0 meters, 4) The height of airtight wall and replacements equals the roof of upper roadway, 5) The normal distance from pneumatic fan to BC is 5.0 meters, 6) Pneumatic fan is fixed on the posterior column of end support, and 5 meters away from the upper beam, 7) The type of pneumatic fan is FQ-80/5.0, set the exit velocity to 25 m/s. 8) The angle between airflow direction of pneumatic fan and main airflow direction is 0°.

Implementation methods of replacement management project are as follows:

1. Using plastic bags with crushed coal to build vertical airtight walls from scraper conveyers to outer side walls in upper and lower roadway respectively, as is shown in Figure 4. The outside part of airtight wall in lower roadway was sprayed by Hassfu in order to improve the effect of preventing air leakage in lower roadway.
2. Measuring the length of Arc AC in Figure 4 to prepare for spraying Hassfu.
3. Spraying Hassfu on the air tight wall downward from the upper roadway, filling vortex zone that is need to be replaced.
4. Because the first-formed outer boundary of replacements Arc AC is relatively coarse. After the initial spraying, in order to improve the efficiency of ventilation, some modifications should be carried out to make the Arc AC more smoothly.
5. Fixing the pneumatic fan to the posterior column of end support, and making the outlet direction of fan to the outer boundary of replacement area, meeting the angle requirement between the airflow direction of pneumatic fan and the main airflow direction.
6. Connecting the pneumatic fan to the air duct in upper roadway so that the fan can be obtained power.

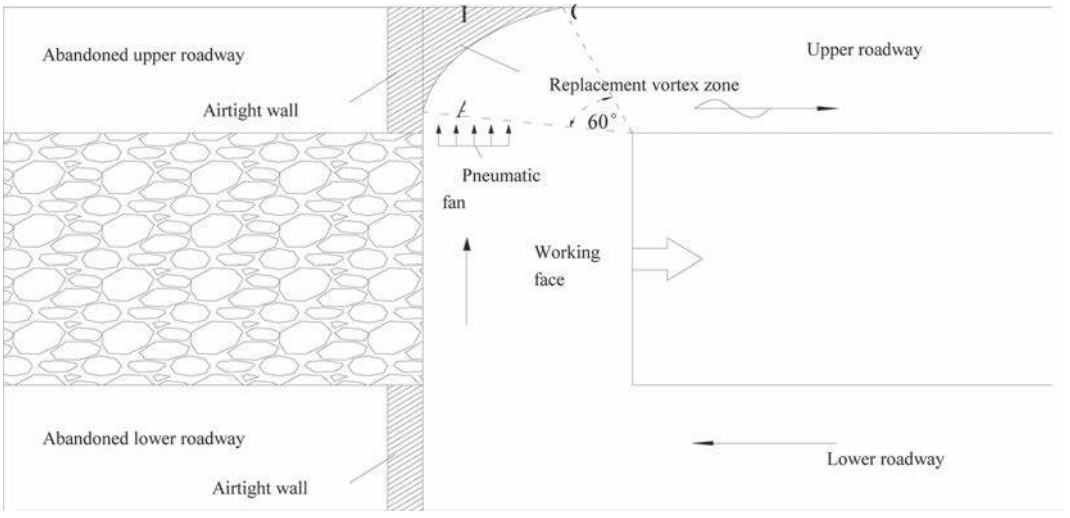

Figure 12. The streamline diagram under different location of pneumatic fan in upper corner field.

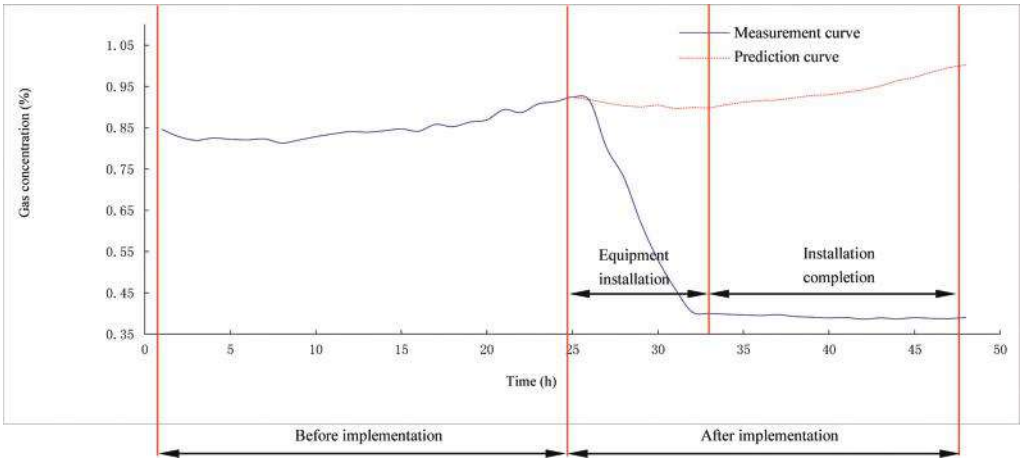

Figure 13. The streamline diagram under different location of pneumatic fan in upper corner field.

5 APPLICATION EFFECT EVALUATION

In order to evaluate the effect of adopting gas control techniques, according to the previous gas concentration before the technology implementation, the later gas concentration can be predicted by grey theory method when the techniquesare not adopted. The gas concentration before adopting gas control techniques in working face S204 at different time is 0.846, 0.822, 0.820, 0.839, 0.858, 0.894, 0.924 respectively, the data is measured in every 4 hours. Figure 5 shows the change curve and the prediction curve of gas concentration in upper corner before and after implementing the technologies.

From the figure we can see that the gas concentration in upper corner shows a rising trend before the technology implementation, but after the technology implementation, the gas concentration decreased sharply at first, and then decreased slowly. There is a big gap between predicted values and measured values, and this gap has a trend of widening. It shows that the technology can effectively control the gas concentration in upper corner. Taking the last data in the day as an example, after the technology implementation, the gas concentration is 0.390%. However, according to the prediction results, the gas concentration will rise to 1.002% without the measures. Therefore, it can be seen that the upper corner gas concentration totally decreased by 61.78% after the measures, thus, the gas controlling effect of this techniques are extremely remarkable.

6 CONCLUSION

1. Upper corner in fully mechanized coal face which uses U-type ventilation is likely to locate in vortex state. A large number of gas emitted from the goaf is hard to enter into the main airflow, which can cause the circular movement and accumulation of gas in upper corner.
2. The installation parameters of pneumatic fan has a significant impact on the effect of eliminating the vortex zone, the optimum parameters of pneumatic fan are as follows: the vertical distance from pneumatic fan to the outer side wall in upper roadway is 5 meters, exit velocity is 25 m/s, the angle between airflow direction of pneumatic fan and main airflow direction is 0°.
3. When vortex zone replacement is adopted to control the upper corner gas, relative technology parameters should be determined based on the parameters of pneumatic fan, and the outer boundary of replacement in replacement area should be made into an arc shape for reducing the wind resistance and facilitating the gas flowing.
4. The comparison between the measured and predicted results shows that the gas concentration in upper corner decreased sharply after implementing the technologies, and the highest decreasing value could reach 61.38%. Desirable results achieved in fully mechanized coal face S204 where gas emission is relatively low.

The prospecting technology for water enrichment of water-inrush geological structure in mine

Wuyang Yang
School of Safety and Engineering, North China Institute of Science and Technology, Sanhe, Hebei, China

ABSTRACT: Karst collapse column, fracture, gob area are the main geologic structures that causing the mining water inrush. Through the comparing research on the application of every kinds of geophysical prospecting, the 3D seismic exploration is adopted to find out the type, size, and distribution of water inrush geological structure, and the transient electromagnetic method and SYT electromagnetic sounding method is used to prospect the watery feature of water inrush structure. The research suggests that the formation water abundance is relative to the size of the apparent resistivity, the watery layer has low apparent resistivity while the low and non-watery layer have high apparent resistivity. The water enrichment of geological structure was analyzed according to horizontal and longitudinal apparent resistivity contour map. This study will provide geological basis for danger evaluation of water inrush. The prospecting results in Huainan mining area suggest that there are two collapse columns in the detection region, the northwest collapse column is free from water and the east one is high with water. The actual laneway shows the data is coincide with the prospecting results, which provides a efficient integrated geophysical method for prospecting the water enrichment of geological structure.

1 OVERVIEW

During the coal mine production, when the excavation roadway runs into karst collapse columns, fault fracture zones, or gob area, the geological hazards, such as coal and gas outburst, roof falling and water-inrush, would be likely to happen. Recent years, several domestic major coal mine accidents are primarily caused by these structures, especially when touching the upper or lower aquifer, the geological structure bearing water would possess the necessary conditions of bursting mine water-inrush (Hu Weiyue & Tian Gan 2010). It is very important to prospect the geological structure type timely and accurately and carry out research on its water enrichment and water storage capacity for predicting mine geological hazards.

2 WATER ENRICHMENT FEATURES OF GEOLOGICAL STRUCTURE AND ITS PROSPECTING METHOD SELECTION

The geological structure, especially the fracture structure, destroys the integrity of aquifuge, meanwhile weakens the water isolating properties and offers a leaking passage to ground water. For different development stages, geological structures are distinct in water enrichment features: the Karst collapse column often forms in areas with soluble rocks. Its water enrichment varies with different development stages. At the rapid development stage of collapse columns, its fillers have not been compacted, featuring high porosity, cavities, water filling and strong water conductivity. Once exposed or touching the affected zone, it will lead to water-inrush accident (Liu Guolin et al. 2009, Yin Shangxian et al. 2008). Upon formation, the fracture will possess the possibility of water enrichment and conductivity, but different types of fracture has different impacts on water enrichment. Featuring weak water enrichment capacity, the compress-shear fracture plane usually contains no water and performs water isolating functions. However, featuring strong water enrichment capacity, the tensor-shear plane usually contains water, especially when communicating with the aquifer. The water enrichment of old mining areas is very complicated and the major reason for water enrichment differences lies in whether the mining areas have been refilled and the saturation of refilling.

Due to the concealment and complexity of water enrichment of geological structures, it is very hard to achieve desired objectives by determining its distribution and properties through conventional geological surveys, especially for the geological structure buried deeply in the ground. For example, it has problems with accuracy for the survey of old mines to be conducted by examining the mining drawing and conducting the survey

of surface cracks (Cheng Jianyuan et al. 2008). Practice shows that the combination of integrated geophysical prospecting and a few underground boreholes can help find out the properties of water-inrush geological structures. At present, the main geophysical prospecting methods to detect geological structure consist of seismic prospecting, transient electromagnetic method, direct current electric method and controlled-source audiomagnetotellurics as well as SYT electromagnetic sounding method (Wang Junru et al. 2002, Ma Zhaofeng 2010, Yu Youshun et al. 2007, Xiang Shoulong 2006, Wang Yanwei et al. 2009). When prospecting on the surface, the seismic prospecting is sensitive to the geological structure type and its occurrence but dull to water enrichment feature. Resistivity method, transient electromagnetic method, controlled-source audiomagnetotellurics and electromagnetic wave method are sensitive to low resistivity good conductor and water enrichment. Due to different working environment of detecting area, different physical properties of rocks and ores, every detecting method has its own application conditions. Single geophysical prospecting may lead to the multiplicity of the outcome, so it is very important to find out efficient prospecting method.

Because of different geological structure depth and surface environment, the combination of geophysical prospecting will have a great impact on the final outcome of its water enrichment prospecting. In several mines of Huainan Coal Mine, the three dimensional seismic method was used to detect the geological structure and finally determined its type, size and distribution range. In Pansan Coal Mine, the corresponding ground location of water-inrush geological structure prospected by seismic prospecting is waterlogged area. It is very hard for many conventional geophysical prospecting methods to prospect on the water, so the combination of transient electromagnetic method and SYT electromagnetic sounding method was selected in this study, to expect a good application effect.

3 GEOPHYSICAL PROSPECTING THEORIES OF WATER ENRICHMENT

3.1 *Transient electromagnetic method*

Transient electromagnetic method solved geological problems by using ungrounded loop or electrode to generate the primary electromagnetic field in pulses and using the loop or grounded electrode to observe the spatial and temporal distribution of the secondary electromagnetic field generated by underground eddy current that was sensed by the first electromagnetic field. this method is sensitive to the underground good conductor medium (low resistivity object), suitable for the evaluation of the water enrichment of faults and fractures, water enrichment prospecting of collapse columns and old mining areas and classifying of roof, floor of coal seam including the aquifer and aquifuge, characterized by alarm to abnormal terrestrial electricity, restriction without electrode contact, strong penetrating and covering ability, subtle volume effect, quick construction and high efficiency. In case of water enrichment, the apparent resistivity will reduce, so this method is an efficient way to explore the hydrogeololgy.

The PROTEM plus 67 transient electromagnetic prospecting system made in Canada was adopted to carry out the detection in the research area on ground.

3.2 *The SYT electromagnetic sounding technique*

The SYT electromagnetic sounding technique is a type of passive electromagnetic system. When the electromagnetic wave which comes from magnetosphere, ionosphere and atmosphere, enters the earth and transmits through underground media, it meets with interfaces with different electric characteristics underground, reflection and penetrating transmission accordingly occurs. A portion of electromagnetic wave is reflected upwards back to the earth surface, the attenuation of its frequency quantum can be calculated through the low frequency window ending frequency formula of the geomagnetism field (Geoff A. Burrell & Leon Peters, JR. 1979, Wang Wenxiang & Yang Wuyang 2002).

$$f = \frac{k\rho}{(H+A)^2} \tag{1}$$

In which, f as the ending frequency (Hz), ρ as the average resistance (Ω·m) of the geological mass at a certain depth, H as the depth (m) of a certain geological mass, k as a constant (9.4×10^5), A as a specific constant, obtained from experiment.

Through derivation, the energy of a certain frequency electromagnetic waves reflects back to the earth surface can be expressed as:

$$V_{fi} = n\frac{\gamma\sigma^2\rho^2}{(H+A)^4} \tag{2}$$

where $n = \dfrac{2\alpha BC_i k^2(10^2-10^3)^2(1-2v)^2}{E^2}$

In formula (2), γ as the reflection factor of interface, σ is the body stress value (MPa), υ is the Poisson

ratio, E is the elasticity amount (GPa), B represents the sensitivity of the transducer (dB), C_i is a variation value which greater than 0 but smaller than 1, α as frequency selection bandwidth of equipment (Hz).

From the formula, it can be known that the reflecting amount of electromagnetic energy is related to the resistivity of underground medium and reflection coefficient of an interface. By calculating the measured data, we can get the apparent resistivity of various depths under each measure point. Research shows that in general, in case of development or water enrichment, the rock crack will be enhanced in absorption of electromagnetic wave, so the energy of electromagnetic wave reflected back weakens a lot and the calculated value of apparent resistivity was low. Accordingly, It can be inferred whether it contains water and its water enrichment degree.

Employ SYT geophysical devices to prospect within the research area.

4 WATER ENRICHMENT PROSPECTING PRACTICE OF WATER-INRUSH GEOLOGICAL STRUCTURE

At present, when prospecting and researching the hydrological conditions in an area, we usually adopted integrated geophysical prospecting. Namely, carry out exploration and investigation of the geological structure and then use electric methods to prospect the water enrichment of the geological structure on ground.

Huainan Coal Mine of research areas is located in the southern margin of the North China plate. Its structural form is a tectonic basin running nearly east-west. The north and south side of the basin collided and formed an imbricate nappe structure and its inside is wide and shows a syncline structure running north-west, forming a synclinorium in Huainan. Pansan Coal Mine is located in the middle of the Huainan synclinorium and the limb of the south-east of Chenqiao anticline and the limb of nappe structure.

From old to new, the layers within the research area are Ordovician system, Carboniferous system, Permian system, Triassic system, Tertiary system and Quaternary system. The coal-bearing stratum is Permo-Carboniferous system. The thin seam of carboniferous Taiyuan group system is nonproductive. The Permian system contains main productive coal seams including 33 coal seams, the primary mineable coal bed are 13–1, 11–2, 8, 4 and 1.

4.1 *Achievements of three-dimensional seismic exploration*

The early three-dimensional seismic exploration found out two geological abnormal objects, located in the northwest and southeast of the prospecting area. In the seismic time section, the standard reflection waves are leaped and disappeared. The layer and seismic attributes of identified geological abnormal objects by seismic exploration shows obvious features of collapse columns. Figure 1 shows the time section of the geological abnormal objects developing at coal seam 8. The number in this figure means the position of the coal seam. Figure 1a is the time section crossing long axis of the collapse column (geological abnormal objects) and its section direction is NE24°. It developed in the west of the prospecting area, featuring small distribution area, elliptic distribution and its long axis was 70 meters and minor axis 40 meters. Figure 1b is the time section along the minor axis of the collapse column (geological abnormal objects) and its section direction is 114°. It developed in the east of the prospecting area, featuring big distribution area and its long axis was about 120 meters and minor axis 100 meters.

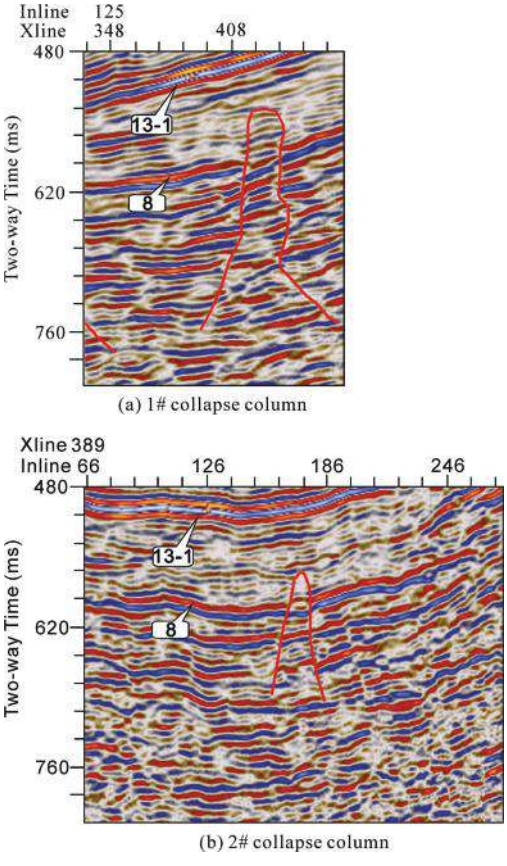

Figure 1. Show up of collapse column on time section of No. 8 coal seam.

The plane configuration of the collapse column was shown in the Figure 2.

4.2 *Prospecting areas and layer positioning*

Take the geological abnormal objects identified by three-dimensional prospecting as the main prospecting area and assign grid measure point in prospecting area with a internal of 25 m, 13 survey lines, 33 measure point on each survey line and a area of 300 m 800 m, as shown in the Figure 2. The dot and line space of the transient electromagnetic method and electromagnetic sounding method are the same.

The transient electromagnetic method equip with high resolution central loop device, emit with a 800 m × 800 m single-turn loop, occupy an area of 200 m^2 and supply with 18 A current and worked within the measure point area covered by the 1/5 of the center loop emitting area. With a sounding depth of 400 m~1500 m, the electromagnetic sounding method prospect point by point.

By prospecting, we should first check up the water enrichment and its distribution area of the geological abnormal objects in the coal strata and then analyze the water enrichment and conductivity of the geological abnormal objects in deep layers as limestone of Taiyuan formation and Ordovician limestone.

4.3 *Data processing method and material interpretation principles*

As for transient electromagnetic method, ρ_s (apparent resistivity) and h_s (apparent depth) can be obtained by conversion. On basis of this, we can conduct topographical correction and elevation correction according to materials concerning measure, geology and misering. The SYT electromagnetic sounding method can form two kinds of drawing by adopting the microcomputer processing software to calculate the apparent resistivity of various depths at each landmark: (1) Contour map of apparent resistivity of horizontal section at different depths used to analyze the coal seam position and the water enrichment and distribution area of layers. (2) Contour map of vertical survey line resistivity used to analyze vertical water enrichment situations.

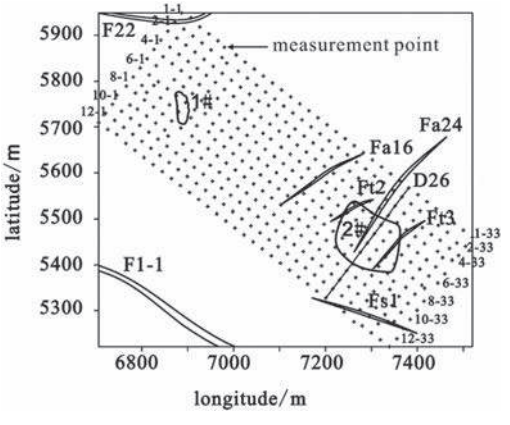

Figure 2. The distribution map of measurement point.

Explain the water enrichment of rock strata. The profile map was based on the horizontal changing features of the apparent resistivity. The explanation principle is: water enrichment area abnormity is the reflection of low resistivity. The stronger the water enrichment is, the low the resistivity is, which was show on the profile map in form of a through featuring "two high and one low". (It is also called "v" style relatively low resistivity). The explanation of the water enrichment area on the profile map is based on the changing of the apparent resistivity. Water enrichment areas are mainly the closed circle of low resistivity on the profile map and the closed circle of minimum is strong water enrichment areas. Moreover, the lower level of the closed circle of minimum is weak water enrichment areas.

Within the prospecting depth, analyze the water enrichment of the target layer through the contour map of horizontal section resistivity at different depths and form a vertical terrestrial electricity section of geological abnormal objects.

4.4 *Geological structure water enrichment analysis*

4.4.1 *Water enrichment of horizontal section*

Take the –650 level coal seam 8 and -800 level limestone of Taiyuan formation as an example for the horizontal section and analyze the structure water enrichment. Figure 3 is –650 level horizontal contour map of apparent resistivity of two method.

Figure 3a is the outcome of SYT electromagnetic sounding method. There is large low value area but the level of 1# collapse column lie in the high value area of apparent resistivity with low water enrichment. The northwest of 2# collapse column is low value area of resistivity with strong water enrichment capacity and meanwhile there is also low value water abundance area in parts of the fault. Figure 3b is the outcome of transient electromagnetic method. The area of 1# collapse column is middle and high resistivity with low water enrichment but the west of 2# collapse column is low value area of apparent resistivity with abundant water. Around the area of the two collapse columns, the outcomes of the two methods are basically the same.

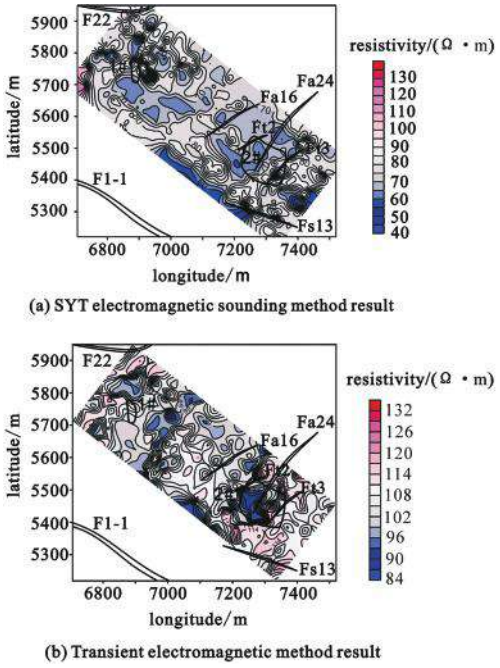

Figure 3. –650 level (8# coal) contour map of horizontal section of apparent resistivity.

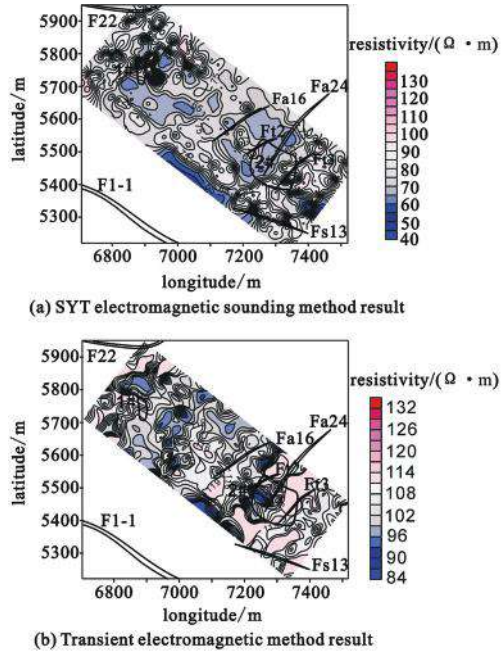

Figure 4. The apparent resistivity contour of –800 level.

The lower of the coal strata lays limestone of Taiyuan formation and Ordovician limestone. In these layers, the water enrichment area water enrichment degree is similar to coal strata.

Figure 4 is the -800 level horizontal contour map of apparent resistivity at the layer of limestone of Taiyuan formation.

In Figure 4a, the area of 1# collapse column is a middle and high value with low water enrichment and the west of 2# collapse column is low value with abundant water, but compared with the coal seam 8, this area is relatively low in water enrichment. In Figure 4b, the abnormal 1# collapse column is high value with scarce water and 2# collapse column lies in low value area. Compared with the coal seam 8, the low value area becomes smaller and part of the west is abundant in water. the prospecting outcome of the two method shows that, at the –800 level, the area of 2# collapse column reduced in the water enrichment.

4.4.2 *Water enrichment of vertical section*

From the analysis of all horizontal sections, we can know that the eastern 2# collapse column has strong water enrichment capacity, so we use the transient electromagnetic method. Figure 5 shows an apparent resistivity sectional map of the D26 line in the middle of the collapse column, it's location is showing in Figure 3. It is a abnormal low resistivity area of –850 to –600 level with a width of 76 m, demonstrating features of the collapse column, which was consistent with the outcome of the horizontal section. Known from the each vertical section, the west of the 2# collapse column has a strong connectivity with the upper and lower aquifer but the southeast relatively weak.

4.5 *Roadway disclosure validation*

Soon after the geophysical prospecting, the roadway of coal seam 8 ran through the geological abnormal part determined by the three-dimensional seismic method. The roadway materials showed that the 1# geological abnormal objective is a collapse column and contains no waters, which is consistent with the explanation of prospecting outcome.

Figure 6 is a sketch of a collapse column section disclosed by coalface. From the disclosure, characterized by mix of big and small rocks, the side of the geological body has the general features of collapse columns. From the analysis of rock fillers, the rock is loose and vulnerable and the rock moves up and has many scoring, which was the result of secondary agent. There was a rock with normal bedding in the middle of the geological abnormal objects, which was caused by the roof falling of the coal seam 8. It has a normal falling

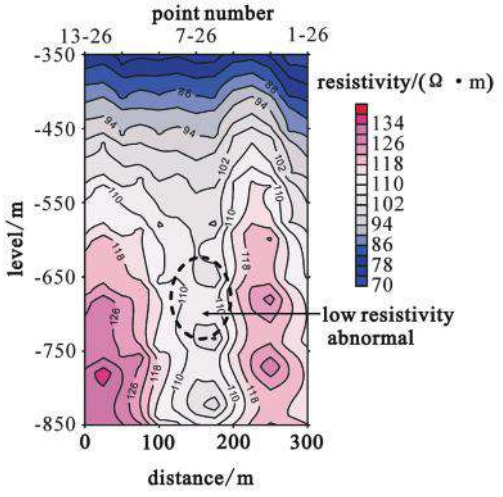

Figure 5. The D26 line apparent resistivity section of Transient Electromagnetic Method.

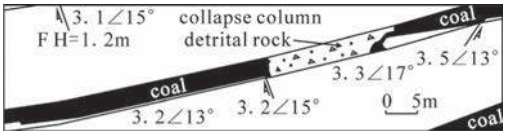

Figure 6. Coalface disclosure Sketch of the 1# collapse column section.

distance with the normal rock strata. The high crack in the geological abnormal object developed and from the distribution, its long axis is 70 m and its minor axis is 30 m.

The water enrichment and distribution range of the 1# collapse column are basically consistent with the prospecting outcome.

The Prospecting outcome of 2# collapse column needs further validation by roadway disclosure.

5 CONCLUSION

Two geological abnormity bodies, named with 1# and 2#, were recognized by three dimensional seismic prospecting method in the prospecting areas. These two abnormity bodies were judged as collapse column from their development features.

The outcome of the transient electromagnetic method and SYT electromagnetic sounding method shows that the 1# collapse column (geological abnormity bodies) in northwest was not water enrich. This outcome was proved by the roadway disclosure. The east of 2# collapse column was partly water abundant and there is hydraulic connection between the upper and lower aquifer in the west of the collapse column and the vertical section through the middle of the collapse column. This needs to be paid more attention in the future roadway excavation.

Materials revealed by some roadway are highly consistent with the outcome of integrated geophysical prospecting. Therefore, combination of transient electromagnetic method and SYT electromagnetic sounding method can be used to find out the water enrichment of the geological structure efficiently, this will provide relatively reliable geological basis for the safety production of coal mines.

Determination of mine ventilation resistance and analysis on ventilation systems in the No. 4 mine of Pingdingshan Coal Field

Yang Hu, Yi Fei Weng & Lin Zhang
Key Laboratory of Mine Disaster Prevention and Control, North China Institute of Science and Technology, Beijing, China

ABSTRACT: Determination of resistance of mine ventilation system is an important part of safety production of coal mine and ventilation safety management, the size of the resistance directly influence the effect of the mine ventilation. In order to understand the No. 4 Mine of Pingdingshan Coal Field mine ventilation resistance and its distribution, the optimization of mine ventilation system, selected major determinations, based on the basis of the barometer method for determination of resistance to the mine, and according to the results of mine ventilation system are analyzed.

1 METHOD FOR DETERMINATION

Currently, the determination of mine ventilation resistance in common use precision digital barometer.

Determination method is mainly divided into two point method and synchronization method. Using the method of base point to determine the mine ventilation resistance, it has the characteristics of time saving, labor saving, fast speed, the more commonly used method is the method of base point. Point method is that a barometer is placed in well or at a point well, at a certain time measured pressure reading and record the time of determination and the changes of surface and atmospheric pressure, which is to correct of pressure data of downhole measurement; Another barometer meter air pressure numerical along pre-selected route by point and records the time measurement.

According to the basic point method, the ventilation resistance between two points by using the following formula calculation (Chen Shaoren & Cheng Jianjun 2006, Chen Zhou, et al 2006):

$$h_i, h_{i+1} = (P_i - P_{i+1}) + (H_i - H_{i+1}) \times (\rho_i + \rho_{i+1}) \times \frac{9.81}{2} + \left(\frac{\rho_i v_i^2}{2} - \frac{\rho_{i+2} v_{i+1}^2}{2} \right) + P_{di} - P_{di+1} \quad (1)$$

where h_i, h_{i+1} i and $i + 1$ are ventilation resistance, *Pa*; P_i, P_{i+1} i and $i + 1$ are absolute pressure value, Pa; H_i, H_{i+1} i and $i + 1$ are elevation, *m*; ρ_i, ρ_{i+1} i and $i + 1$ are air density, Kg/m^3; v_i, v_{i+1} i and $i + 1$ are wind speed, *m/s*; P_{di}, P_{di+1} i and $i + 1$ are ground atmospheric pressure variation value when reading, *Pa*.

2 DETERMINATION OF ROUTE CHOICE AND THE ARRANGEMENT OF MEASURING POINT

Determination of route is from the inlet shaft through air location to return all flow route without wellhead installation drag facilities a flow line, it can control the whole network of a ventilation system, and can facilitate the understanding of all kinds of roadway resistance distribution.

Measuring point layout should meet the following requirements:

1. Section is regular, consistent with the wind conditions.
2. Local resistance measuring point road material requirement is: before 3–4 times and 8–12 times after lane width.
3. Measuring point should be located where elevation locations can be found.
4. The measuring distance between two adjacent points is generally 200 *meters*, instrument readings should be greater than 19.62 *Pa*.
5. Measuring point should be located in a safe place.

3 DATA PROCESSING

3.1 *Parameter calculation*

When the working of underground actual measurement end, we must carefully collate and calculate

the actual measurement data (Cheng genyin, et al 2005).

1. Air volume calculation

$$Q = S \times V \tag{2}$$

Where S is Roadway break area of test point, m^2; V is mean wind speed of test point, m/s.

2. Ventilation resistance

$$h_i, h_{i+1} = \left(P_i - P_{i+1}\right) + \left(H_i - H_{i+1}\right) \times \left(\rho_i + \rho_{i+1}\right) \times \frac{9.81}{2} + \left(\frac{\rho_i v_i^2}{2} - \frac{\rho_{i+2} v_{i+1}^2}{2}\right) + P_{di} - P_{di+1}$$

3. Roadway windage

$$R_{1-2} = \frac{h_{i,i+1}}{Q^2} \qquad NS^2/m^8 \tag{3}$$

Roadway standard windage

$$R_{0,1-2} = \frac{\rho_0 R_{1-2}}{\rho_{1-2}} \qquad NS^2/m^8 \tag{4}$$

Where ρ_0 is reference value of underground air density, $\rho_0 = 1.2\ mg/m^3$; $\rho_{1\text{-}2}$ is average of the air density between two section, mg/m^3.

4. Roadway meters wind resistance

$$R_{r100} = \frac{100 R_r}{L_{1-2}} \qquad NS^2/m^8 \tag{5}$$

Where R_r is friction windage of measured straight roadway, NS^2/m^8; $L_{1\text{-}2}$ is distance between the two measuring points, m.

5. Coefficient of frictional resistance

$$\alpha = \frac{R_r S^3}{LU} \qquad NS^2/m^4 \tag{6}$$

Where L is length of measuring roadway, m; U is circumference of the measuring roadway point section, m; Standard value of airway friction resistance factor

$$\alpha_0 = \frac{\alpha \rho_0}{\rho_{1-2}} \qquad NS^2/m^4 \tag{7}$$

3.2 *Data processing principle*

1. The air volume between the measurement section, roadway basal area and perimeter take the calculated average between two points.
2. The air volume is too small or the roadway with throttles, if slightly speed wind table cannot be started, the air flow according to the node flow closed principle, composed of adjacent tunnel air volume calculation.
3. Due to the resistance measurement time is long, everyday air volume has changed, even the same day, a measuring section due to the approaching tunnel door open or vehicles, air volume changes, may cause joint air flow imbalance, the volume takes two point average.
4. If the actual measurement data of manifest error, we use the same lane other measured results by analogy. Small wind amount measuring section, differential pressure is too small, the reading error is larger, this segment has no analogy.
5. The existence of local resistance measured not by analogy.

4 ANALYSIS OF THE RESULTS

4.1 *Resistance measurement result analysis*

In May 25, 2012, the No. 4 Mine of Pingdingshan Coal Mine finished the ventilation resistance, resistance measurement result analysis and opinion as follows:

1. WuJiu mining area of the first level determination results for 4023 *Pa*, compared to draught fan working pressure 3980 *Pa*, WuJiu mining area in measuring resistance of main draught fan working pressure is larger than 43 *Pa*, the error of 1.08%, in the allowable error less than ±5%.
2. The JiSan mining area of the second level determination results for 4067 *Pa*, and draught fan working pressure 4010 *Pa* (Dongtai), measuring the resistance of main draught fan working pressure greater than 57 *Pa*, error is 1.42%, the allowable error of less than ±5%. Determination of GengYi mining area are: 3723 *Pa*, and draught fan working pressure 3760 *Pa* (West), measuring the resistance of main draught fan working pressure is smaller than 37 *Pa*, error is 0.99%, the allowable error of less than ±5%.
3. In third level of determination results for 1770 *Pa*, and compared to draught fan working pressure the 1780 *Pa*, measuring resistance than the main draught fan working pressure too small for 10 *Pa*, error is 0.56%, the allowable error of less than ±5%. Ding Jiu area determination results for: 1781 *Pa*, 1780 *Pa* compared with draught fan working pressure, measurement of resistance than the main draught fan working pressure too small for 1 *Pa*, error is 0.05%, the allowable error of less than ±5%.

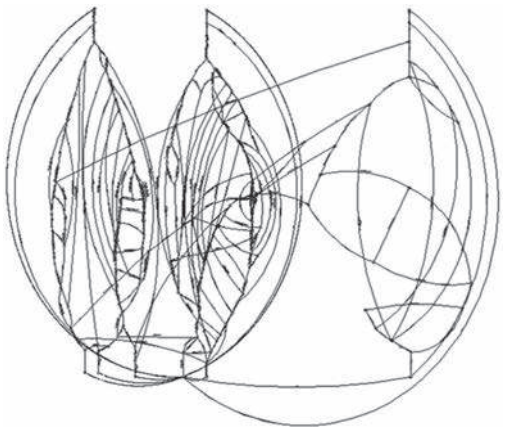

Figure 1. Mine ventilation chart.

Through the calculation, the three shaft system errors are within the allowable error less than ± 5%, basically conforms to the mine ventilation reality, the results can be used for the ventilation system transformation.

4.2 *Mine each air shaft system resistance distribution analysis*

Through the calculation of mine ventilation network and analysis of mine, the WuJiu mining area into, use, air return section resistance percentage of 14.21%:41.9%:43.89%, the JISan mining area into, use, air return section resistance percentage 22.67%:51.45%:25.88%, the GengYi mining area into, use, air return section resistance, percentage of 25.81%: 37.14%:37.05%; the third level into the mining area, use, return period of resistance percentage of 68.92%:18.18%:12.9%; the DingJiu mining area into, use, air return section resistance percentage 54.54%:36.83%:8.63%; The individual location of total return is affected by mining roadway in serious deformation, the roadway contraction section smaller, and the bend more, causing the return air resistance is too large, should focus on the main return airway ventilation resistance area for the expansion and maintenance of transformation, in order to reduce the resistance of ventilation. Mine ventilation network solution shown below.

5 CONCLUSION

1. For a air volume 24750 m^3/min old mine, ventilation resistance, 4010 *Pa*, it indicate the ventilation system line is longer, resistance is bigger. For high resistance of roadway must accelerate roadway repair strength, timing fixed object specific arrangements, to reduce the resistance of ventilation system, better play the main draught fan performance.
2. To further strengthen the management of mine ventilation technology, improve the basic technical work, improve the whole level of management of "one ventilation and three prevention".

Design of mine monitoring system based on ZigBee and CAN

Deguo Liu & Jinshun Wu
North China Institute of Science and Technology, East Yanjiao, Beijing, China

Hao Liang
Department of Scientific Research Collaboration of Jiuquan Satellite Launch Center, East Yanjiao, Beijing, China

ABSTRACT: The current coal monitoring system is analyzed in the paper. We design the new structure of coal wireless monitoring system based on the ZigBee and CAN Technology. The coordinator node is designed using 89C51 and CC2420. Further more, the router node and the end node are designed using CC2530 and the sensors such as temperature, humidity and gas sensors.

1 INTRODUCTION

The environmental parameters in coal mining should be monitored in real time. The current monitoring system in coal mining collects the environmental information from the sensors by the cables. The sensors and the monitoring centers are connected by the cables directly. The information of temperature, humidity and gas is sent to the monitoring centers on the ground. Now, with the developments of the ZigBee and CAN technology, the new wireless monitoring system combining the ZigBee and CAN is studied. The environmental information is collected by the wireless sensor networks underground. Then the information is sent to the ground monitoring centers in real time by the CAN bus. The new wireless monitoring system is low power consumption and flexibility. The system use wireless network and CAN technology. It is easy to lay and expand. The environment information can be transmitted over long distance. The system is suitable for the monitoring of mine environment.

2 SYSTEM VIEW

The current cable monitoring system which is connected by the cables underground demonstrated in Figure 1. The monitoring system includes the sensors, the monitoring stations, the Bus, the Modem and the host monitoring computers. The information is collected by the sensors underground and then the information is sent to the stations by the cables. The information is sent to the modem by the Bus and the information is sent to the host computers on the ground by the cables or optical cables.

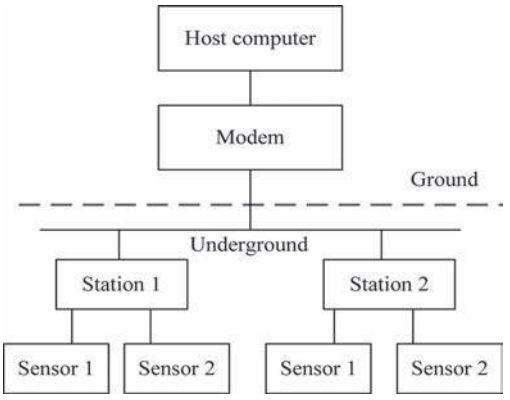

Figure 1. Current monitoring system.

The stations and the sensors are connected directly with the cables. Due to the limitations of the mine, maybe it is difficult to lay the cables between the stations and the sensors somewhere. On the other hand, the cable will perish or be eroded, that is hidden danger to monitoring system. Therefore, there are some defaults for the system with the cables.

The monitoring system based on ZigBee and CAN technology is shown in Figure 2. The monitoring system includes the host computer, the CAN bus, the coordinator, the router node and the end node.

The environmental information is collected by the end nodes directly. The end node is composed of the sensors and the microprocessor which possesses the Zigbee protocol stack. The end nodes which are carried by the workers or the mechanical equipments in the mine collect the environmental

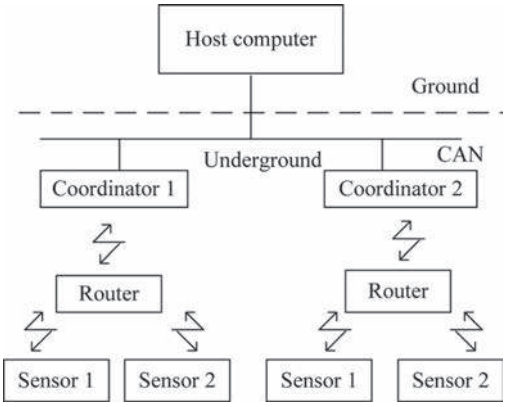

Figure 2. Monitoring system based on ZigBee and CAN technology.

information. The information is transmitted to the router node or the coordinator over the wireless. The end nodes are the reduced function devices (RFD) which can only collect and transmit the information.

The environmental information which is collected from the router nodes directly or collected from the end nodes can be routed to the coordinator. In comparison with the end nodes, the router nodes have the lager transmission power and they are fixed on the wall of the tunnels. The router nodes are the full function devices due to the routing function.

The coordinator node receives the information from the router nodes over the wireless, meanwhile, it converges and deal with the data. Then, the data is transmitted to the host computer over the ground. The coordinator is the important node in the system. The coordinator which is the full functional device (FFD) builds the networks and receives the data from the router nodes or end nodes. The coordinator node can also control the router nodes or end nodes.

The host computer with the monitoring software deals with the data from the mine. The data can be analyzed and stored. Then it can also be shown by the LCD screen or be printed in real time. The data is transmitted between the host computer and the coordinators by the CAN bus. The CAN bus adapts the non-destructive arbitration technique, which can avoid the bus collision. It ensures the capacity and the rate of the data. From Figure 2, we see that the data is transmitted between the coordinator node and the router node or the end node over the wireless. It is flexible to install the node underground over the wireless. Further more, it avoids the dangers of the cables such as the aging, the breakage and the corrosion of the cables. Therefore the wireless monitoring system is suitable to the mine.

3 THE COORDINATOR NODE

From the analysis above, we can conclude that the coordinator is an important node which collect and transmit the data. The structure of the coordinator is shown in Figure 3.

The coordinator node use 89C51 which is from the Intel Company as the microprocessor. The CAN bus controller use SJA1000 from the Philips company. Since the 51 series microprocessor can connect directly with the CAN bus controller, it is easier to design the hardware. In order to use 51 series microprocessor, the "MODE" foot of SJA1000 should be set to high level. Due to the special environment underground, the jamming of the wireless network is serious. The CAN bus between the host computer and the coordinator node can decrease the jamming underground. The Highly integrated CAN controllers SJA1000 can realize the bus access priority and hardware filter. The PCA82C250 which is the transceiver for CAN bus can support more than 110 nodes. The communication distance, the precision and reliability are improved by the PCA82C250 transceiver.

In order to enhance the anti-interference capability of the system, the optical isolators 6 N137 module is adapted between the transceiver and controller of the CAN bus.. The CC2420 module is the RF transceiver between the coordinator and the router node or the end node. First the RF transceiver CC2420 receives the information and transmit to the 80C51 microprocessor, then the information is transmitted to the host computer by the CAN bus. The keyboard module, the LCD display module and the alarm module are designed on

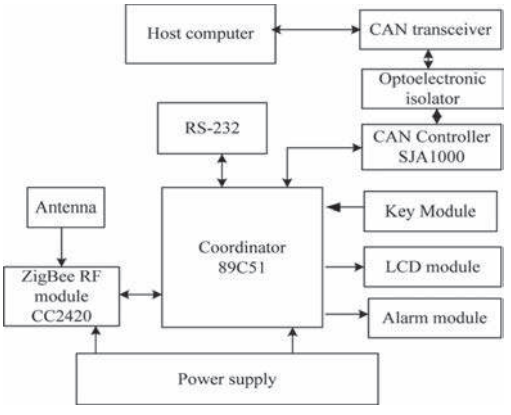

Figure 3. The Coordinator node.

the coordinator node. The environmental parameters upper and lower limits are set by the keyboard module. The LCD displays the function menu and the environmental parameters. When the end node is separated from the network or the environmental parameters overrun the limits, the alarm module will send alarm information. The RS232 is used to debug the program.

4 THE ROUTER NODE

The router node collects the environmental parameters and relays the information. The structure of the router node is shown in Figure 4.

The router node includes the CC2530 chip, the sensors, keyboard and the led. The CC2530 is a true system-on-chip solution for ZigBee applications. The CC2530 combines the excellent performance of a leading RF transceiver with an industry-stand enhanced 8051 MCU and in-system programmable flash memory.

The sensor monitors the gas, the temperature and the humidity underground. In order to detect the methane, the TGS813 which is a tin dioxide (SnO_2) semiconductor is a general purpose sensor with sensitivity to a wide range of combustible gases. The conductivity of SnO_2 is low in clean air. But the conductivity of SnO_2 increases depending on the detectable gas concentration in the air. TGS813 has the long life and low cost. The sensor module can convert the change in conductivity to an output signal according to the gas concentration.

The digital temperature-humidity sensor SHT11 is used to detect the temperature and the humidity underground. The temperature and the humidity can be detected by the SHT11 sensor at the same time. The operating range of the temperature is –40~+123.8°C, the temperature accuracy is ±0.4°C. The operating range of the humidity is 0~100%RH, the humidity accuracy is 3%RH. The information of the humidity and the temperature is transmitted to CC2530 micro processor by the SCK and the DATA line. Then the environmental information is sent to the coordinator node bye the antenna. It will explode when the concentration of the methane is 5%–15%. Therefore, the router node will alarm when the concentration of the methane is more than 3%.

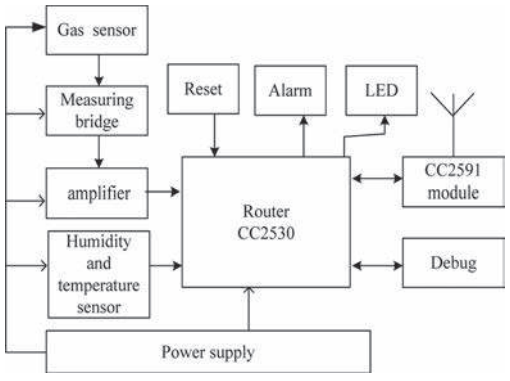

Figure 4. The Router node.

In order to improve the sensitivity and the transmission power, the CC2591 as the broadband RF front end is used. The TPS73033 power supply is used in the design. The TPS73033 module can change the input volt 3.3~6V to the steady output volt 3.3V.

5 THE END NODE

The end node is only responsible for the collection of the environmental parameters. The structure of the end node is similar to the router node. In order to reduce the cost, the end node has no the module of broadband RF front end CC2591. The transmission range of end node is shorter than that of the router node. The end nodes collect only the information. The router node can not only collect the information but also relay the information.

6 CONCLUSION

The current monitoring system underground is analyzed. Then the new monitoring system underground based the ZigBee and the CAN technology is discussed. The coordinator node, the router node and the end node are designed. The new monitoring system base on the Zigbee and CAN technology underground can monitor the environmental parameter underground and display the information. The new system is suitable to the complex environment underground and it will play a great role in the coal mine safety monitoring system.

Development and application of gel foam materials for fire prevention and extinguishing

Zhenhua Xie, Tingting Luan & Yu Zhang
Civil and Environment Engineering School, University of Science and Technology Beijing, Beijing, China

ABSTRACT: Because the geological conditions of coal in goaf with high dip and hard roof are complex, and the law of air leakage is complicated and changeful, so the risk of coal spontaneous combustion in goaf is higher, and need to take effective measures for fire prevention and extinguishing. Through theoretical analysis and experimental research, this paper determines the appropriate foaming agent, foam-stabilizing agent, gelling agent, cross-linking agent in gel foam materials. The optimum formula for gel foam materials by experimental study is: foaming agent compound with sodium laureate and SDS at the ratio of 2:3, concentration for 0.6%; foam-stabilizing agent CMC concentration for 0.1%; gelling agent AM concentration for 0.3%; cross-linking agent MBA concentration for 0.3%. This gel foam materials have excellent inhibitor performance and sealing performance for the spontaneous combustion prevention. The gel foam materials were grouted to goaf of 7162 working face in LongDong coal mine for fire prevention and extinguishing. The results in monitoring sites show that the gel foam materials had effectively restrained spontaneous combustion in goaf, and guaranteed the safety mining.

1 INTRODUCTION

Coal spontaneous combustion is one of the major disasters in coal mines, wasting a lot of coal resources, and affecting the coal mine safety production. At present, the process of fully mechanized top coal caving, which has advantages of high mining intensity, high efficiency, good economic returns and etc., are widely used in coal mining, but the caving height of fully mechanized face goaf is big, float coal is more and uneven distribution, which result in the increase of spontaneous combustion risk in goaf (Yan Wei 2010). Especially the goaf with high dip angle and hard roof caving has a greater risk of coal spontaneous combustion. The main reasons are that: fully mechanized mining technology is difficult, which is easy to cause advance speed of the working face slowly or stopping mining and make the oxidation time of floating coal too long in goaf; in addition, coal seam roof is hard, and coal pillar is easy to compression crushing, and the caving filling in goaf is not dense, which increases air leakage. Therefore, we must take the targeted measures for fire prevention and extinguishing to control coal spontaneous combustion in goaf.

At present, conventional methods to control coal spontaneous combustion in goaf include grouting, nitrogen injection, inhibitors injection and etc. fire-fighting technology (Qin Botao 2007, Chan Yafei 2008). In recent years, by the study of coal spontaneous combustion mechanism and new materials, new fire prevention and extinguishing technology can be implemented and applied, such as gel (Deng Jun 2011), atomization inhibitor (Deng Jun 2012), three-phase foam (Xie Zhenhua 2011), etc. but as a result of the restriction of technical and economic aspects, while these materials is used in single, there are still shortcomings such as high cost, incomprehensive effect, and they also cannot satisfy requirements for fire prevention and extinguishing of large dip angle, hard roof caving mining face and etc. special conditions.

Through theoretical analysis and experimental research, the paper developed a fire prevention and extinguishing material with the advantages of synthetic gel and three-phase foam, namely, a fire prevention and extinguishing material of gel and foam, which has excellent inhibitor performance to coal spontaneous combustion and sealing performance to air leakage in goaf. Using gel foam materials can effectively prevent the coal spontaneous combustion in goaf with large dip angle and hard roof caving of 7162 working face in Long Dong coal mine.

2 THE FORMULA OF GEL FOAM MATERIALS FOR FIRE PREVENTION AND EXTINGUISHING

2.1 *Composition and fundamental characters of gel foam*

Gel foam is a kind of decentralized system of which gas dispersed evenly in the gel, which is produced

by the reaction of gelling agent, foaming agent, foam-stabilizing agent, cross-linking agent, etc (A.M.Tafreshi 1999). After gel foam fluid formed foam under the action of foaming agent, the gelling agent and cross-linking agent distributing evenly in the foam wall react cross-linking, forming the gel of cubic reticular structure containing gas. The liquid phase of the gel foam is water, and generally gas phase is nitrogen.

Gel foam combines the advantages of gel and three-phase foam, and overcomes their shortcomings, its character mainly contains:

1. The liquidity of pure gel is bad, and the flow rate and diffusion range is small. Gel foam can be transported smoothly higher and farther range after adding gel into gas phase medium.
2. Large flow gel foam can cover the loose coal in goaf, and have a good effect on cooling and insulating air. So it can effectively restrain spontaneous combustion, and guarantee the highly efficient and safe backstopping.
3. Gel foam has good sealing performance. When the foam is broken, the gel in the foam continues to play a role of sealing and covering, and ensure the constancy and validity of sealing.
4. Gel foam expansion ratio is high, making the gel foam cost of unit volume greatly decreased.

2.2 *The research of gel foam formula*

After gelling agent and foaming agent dissolving and being stirred evenly, we add cross-linking agent and foam-stabling agent and agents form foam rapidly through mechanically foaming. The gelling agent and cross-linking agent in the foam wall set off cross-linking reaction, forming three-dimensional network spatial structure, making up the skeleton of foam, which makes gel foam have incomparable stability and strength than common water-based foam (Asghari, K. 2005, Gupta, D.V.S. 2005).

2.2.1 *The selection of foaming agent and concentration determination*

According to the influencing factors of gel foam performance and selecting principle of foaming agent (Chen Qibin 2007, Gu Xuerong 2005, Romero-Zeron, L.2006), and on the basic of fully analysis and comparison, we select 7 kinds of foaming agents—sodium dodecyl benzene sulfonate (ABS), lauryl sodium sulfate (SDS), sodium laurate, Dodecyl Trimethyl Ammonium Chloride (DTAC), fatty alcohol polyoxyethylene lauryl ether sulfate sodium (AES), A alkenyl sulfonic acid sodium (AOS), Cetyl Trimethyl Ammonium Bromide (CTAB)—to measure their foaming capacity. Take a certain quality of foaming agent by analytical balance, putting it into a 250 mL beaker, then add 50 mL water from LongDong coal mine, dissolving in the constant temperature water bath to ensure that the temperature of foaming-agent water solution can stay at 25°C. After foaming one minute in the Waring Blender, pouring it into graduated cylinder and measuring foaming volume. The experimental results are shown as Fig. 1.

From Fig. 1 we can see that with the increase of concentration of foaming agent, foam volume also increases rapidly; and when the concentration of foaming agent reach a certain value. This is because when the concentration of foaming agent reaches its critical micelle concentration, the gas-liquid interface has been full of foaming agent, and the surface tension of solution will no longer continue to decline.

Under the same concentration of foaming agent, the foaming capacity of sodium laurate, SDS and DTAC is significantly stronger. They can respectively reach 460 mL, 500 mL and 480 mL when the concentration is 0.6%. This is mainly because the surface tension of the solution is lower than the solution containing ABS, AES, AOS and CTAB after adding sodium laurate, SDS and DTAC, which reduces the surface energy of the liquid and is conductive to foam.

Then select sodium laurate, SDS and DTAC to compound with each other. We can know from the experimental results that foaming agent after compounding has better effect on foam expansion and foam stability than single foaming agent. Foaming performance is the best compound at the ratio of 2:3~3:2, and its foaming capacity firstly increases then decreases. We can see by comparing 3 kinds of compounding results that compound with sodium laureate and SDS at the ratio of 2:3 has the best performance, and foam volume reaches up to 630 mL, significantly higher than the other two 460 mL and 500 mL. So we select sodium laurate and SDS to be foaming agent compound at the ratio of 2:3.

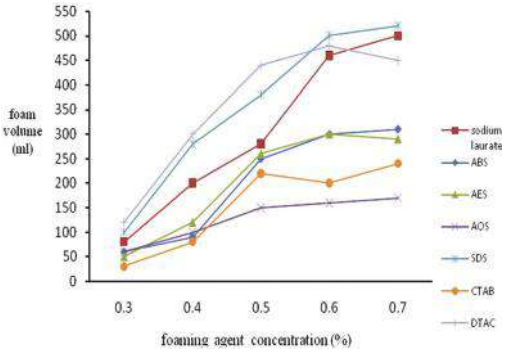

Figure 1. Foaming capacity curve of foaming agent.

Finally, research the influence of concentration of foaming agent on foaming performance by change the concentration of foaming agent. The results are shown as Fig. 2.

We can know from Fig. 2 that with the increasing of the concentration of foaming agent, foaming performance also enhances. When the concentration is greater than 0.6%, foam volume increases slowly. This is because when the concentration exceeds 0.6%, the surface tension of the seriflux falls difficultly, and foaming agent has formed micelles in solution. So we finally determine the concentration of the foaming agent being 0.6%.

2.2.2 *The selection of foam-stabilizing agent and concentration determination*

According to the foam-stabilizing mechanism and demand of foam-stabilizing agent, and through analysis and comparison (Wang Qiwei 2008, Dong, Y.S. 2005), we select 6 kinds of foam-stabilizing agents—starch, glycerol, poval (PVA), Polyacrylamide (PAM), Hydroxyl Ethyl Cellulose (HEC), Carboxy Methyl Cellulose (CMC)—to measure their foam-stabilizing capacity. Measure the foam-stabilizing effect under the same condition of foaming agent compound sodium laurate and SDS at a ratio of 3:2 (concentration for 0.6%) and concentration of foam-stabilizing agent for 0.1%. The results are shown as Table 1.

We can see from Table 1 that the foam produced by system containing HEC and CMC have the longest stability time (more than 4h), but adding different foam-stabilizing agent has influence of different level on system foaming. The foam-stabilizing mechanism of starch, PVA, PAM and HEC is to increase the viscosity of foam and decrease the liquidity of foam. The increasing of foam liquid viscosity are contradictory to the decreasing of surface tension, bringing some bad effects on foaming. Although glycerol has some function of foam-boosting, its foam-stabilizing performance is low, and can't meet the requirement of the field use. The adding of CMC can increase the viscosity of foam liquid, reduce the liquidity; at the same time, it can enhance the structural stability of foam liquidity membrane, making foaming agent molecules distributing orderly on the foam liquidity membrane, and giving foam good elasticity and self-healing ability. So we select CMC to be foam-stabilizing agent. The best concentration of CMC is 0.1% by concentration experiment.

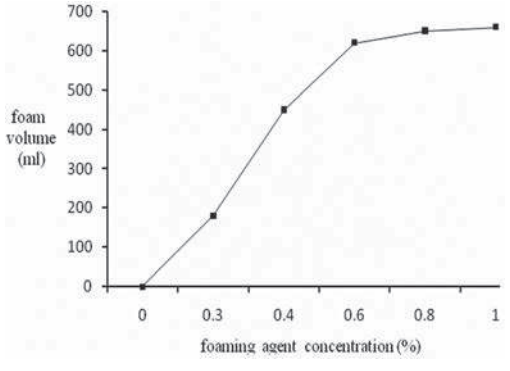

Figure 2. Foaming capacity curve of foaming agent.

Table 1. Different foaming-stabilizing agents' influence on foam volume and stability time.

Foam-stabilizing agent	Starch	Glycerol	PVA	PAM	HEC	CMC
foaming volume (mL)	480	650	520	560	510	620
foamstabilizing time (min)	180	190	210	225	315	295

Table 2. Components concentration relational tables of gelling time and gel foam.

Gelling agent	Concentration (‰)	Cross-linking agent	Concentration (‰)	Gelling time (min)
AM	3	MBA	1	–
	3		2	72
	3		3	14
	4		1	52
	4		2	25
	4		3	8

2.2.3 *Concentration determination of gelling agent and cross-linking agent*

Through theoretical analysis and literature analysis (He Li 2006), select Acrylamide (AM) to be gelling agent and N, N'-methylene-bis-acrylamide to be cross-linking agent, and measure gel time and gelatinous modality of different concentrations. Measure gel time of the respectively reaction of gelling agent AM at 2 concentrations of 0.3% and 0.4% and cross-linking agent at 3 concentrations of 0.1%,0.2% and 0.3%. The results are shown as Table 2.

It will be best that the gel time of gelling agent and cross-linking agent is shorter than the half-time of surfactant forming foam, but it can't be too fast. There is an induction period in the cross-linking

reaction between adding cross-linking agent into gelling agent and viscosity rising. After that, the viscosity increases along with the change of time, and go through a steady-state cross-linking stage.

We can know from Table 2 that under the condition of the same concentration, gel time decreases with the increasing of the concentration of cross-linking agent. When the concentration of gelling agent is 0.3% and the concentration of cross-linking agent is 0.1%, it can't gel; when the concentration of MBA increases to 0.2%, it can gel after 72 min, but its gelling is weak and can not conform to the requirements of the use; when the concentration of MBA increases to 0.3%, gelling time is 14 min, and gel time is appropriate, and gel strength can also meet the requirements. When the concentration of gelling agent is 0.4% and the concentration of cross-linking agent is 0.1%, it takes 52 min to gel, and it is too long; when the concentration of MBA increases to 0.2%, under the condition of less gelling agent and cross-linking agent, gelling time is just 8 min, so it is bad for long distance pipeline transportation. So, both of the two kinds of formula of gelling agent concentration for 0.3%+cross-linking agent concentration for 0.3% and gelling agent concentration for 0.4%+cross-linking agent concentration for 0.2% can meet the requirements of gel foam.

2.2.4 *Determination of gel foam formula*

Determine the best formula of gel foam by comparing experimental results of foam volume, and check the influence of each component on the gel foam. The experimental results are shown as Table 3.

The foaming capacity of the gel foam increases with the increasing of the concentration of the foaming agent, and up to a certain concentration, the concentration of the foaming agent increases but its foaming capacity basically remain unchanged, and 6‰ is the best concentration; but the foam volume decreases with the increasing of the concentration of gelling agent, because the adding of gelling agent makes system viscosity increase, and make it more difficult to overcome surface tension forming foam; concentration of cross-linking agent have less influence on the foaming capacity. It needs some time for cross-linking agent and gelling agent react, to make gelling agent react cross-linking to form gel.

The optimum formula for gel foam materials by experimental study: foaming agent compound with sodium laureate and SDS at the ratio of 2:3, concentration for 0.6%; foam-stabilizing agent CMC concentration for 0.1%; gelling agent AM concentration for 0.3%; cross-linking agent MBA concentration for 0.3%.

3 PERFORMANCE TEST OF GEL FOAM MATERIALS FOR FIRE PREVENTION AND EXTINGUISHING

3.1 *Inhibitor performance test of gel foam*

At present, there are two common methods of testing the inhibitor performance of materials for fire prevention and extinguishing: one is testing the percentage ET of the amount difference of CO released before and after the coal sample processed by inhibiting and the amount of CO released coal sample unprocessed by inhibiting to be the inhibitor rate (Tian Zhaojun 2010); and the other one is testing the percentage Eco of the temperature difference of coal sample before and after processed by inhibiting and the temperature of the coal sample unprocessed to be the inhibitor rate (Lu Wei 2005, Glenn, Gregory M. 2008,).

Experimental facility is shown as Fig. 3. It includes gas supplying system, programmed temperature system and sample analysis. Gas supply system includes air compressor pump, reducing valve, flow control valve and display instrument, and connect them with copper tube in turn. Programmed temperature system includes thermostat and programmed heating controlling facility. Install spiral preheating tube and sample can in the thermostat, and the temperature controlling precision is 0.1°C.

The experimental coal sample is from 7162 working face in LongDong coal mine. Break up the

Table 3. Experiment results of gel foam formula.

Experiment	Composite foaming agent concentration (%)	Foam-Stabilizing concent ration (%)	Gelling agent concentration (%)	Cross-linking agent concentration (%)	Faom Volume (mL)
Formula 1	0.6	0.1	0.3	0.3	620
Formula 2	0.6	0.1	0.4	0.2	570

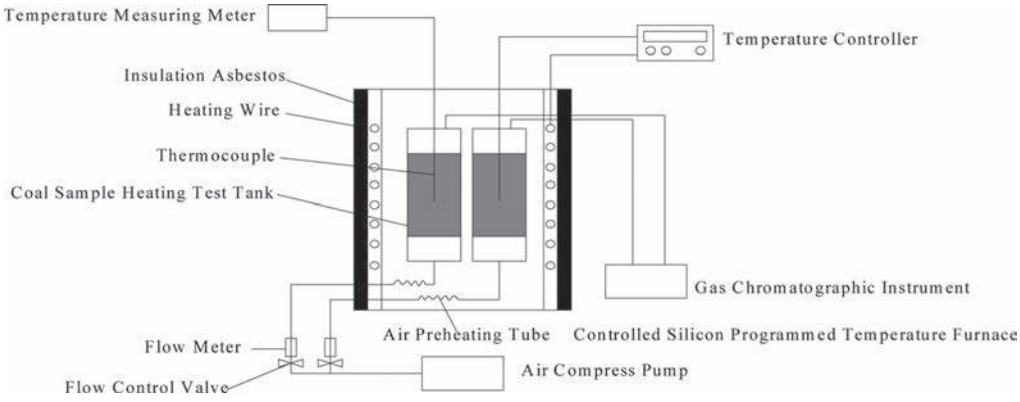

Figure 3. Testing device diagram of the inhibitor performance.

coal sample, take and compound the same weight of coal sample of different granularities which are <0.9 mm, 0.9~3 mm, 3~5 mm, 5~7 mm and 7~10 mm as the experimental coal sample. Add $CaCl_2$ into the mine sample to compare, because $CaCl_2$ is traditional inhibitor for the spontaneous combustion agent. Weigh up three portions 1.0 kg coal sample, and compound respectively: the raw coal sample, coal sample with 10% $CaCl_2$, coal sample with 1% gel foam. After compounding coal sample and inhibitor evenly, ventilate and dry it in room temperature for 24h to constant weight. Put the sample after processing into the coal sample can, under the condition of not passing oxygen into it, and set temperature control furnace running at 30°C constantly. When the temperature of coal sample rises up to 30°C, pass dry air at s flow rate of 100 mL/min, and start programmed temperature and the heating rate is 1°C/min.

Record the coal sample temperature per 15 min, and analysis the content of indicator gas CO by using gas chromatograph instrument. And we get three portions of the coal sample temperature changing rule with the increasing temperature of furnace and the indicator gas CO released in the process of oxidizing and heating up. It is shown as Fig. 4.

We can know from Fig. 4 that under the same temperature conditions, the CO released coal samples processed by the gel foam is much lower than the raw coal samples. The inhibitor rate Eco is 45% at 100°C. We can know from the data of temperature changing (data omitted) temperature of the coal sample processed by the gel foam and $CaCl_2$ is lower than the raw coal sample in the same heating time, and the inhibitor performance of gel foam excels significantly than $CaCl_2$. When the temperature of furnace is 180°C, the inhibitor performance of gel foam is the best (ET = 25%).

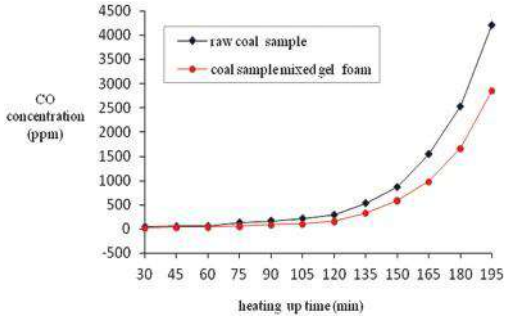

Figure 4. Relations between CO concentration and coal-sample heating-up time.

3.2 *Sealing performance test of gel foam*

Put the coal sample processed by the gel foam into the homemade test-tube of sealing pressure, and make sure the dry air at the entrance of the tube decompressed and pressure controlled by the reducing valve, and test the pressure at the entrance of the tube by pressure gauge. Test the pressure at the exit of the tube after sealed by the coal sample processed by gel foam by pressure gauge. Figure out the pressure difference between entrance and exit, and assess the sealing performance of gel foam.

Break up the new coal sample, take and compound the same weight of coal sample of different granularities which are <0.9 mm, 0.9~3 mm, 3~5 mm, 5~7 mm and 7~10 mm as the experimental coal sample. Weigh up three portions 1.0 kg coal sample, and compound respectively: the raw coal sample, coal sample with 1% water-based foam, coal sample with 1% gel foam. Put the coal samples into the test tube, and seal the whole system. Improve the pressure at

the entrance of the tube gradually, and get the pressure difference between entrance and exit. Test the minimum pressure when the gas breakthrough the block.

After putting the raw coal sample into the test tube, the pressure difference between the two ends of the test tube has no obvious rise, and once gas appears at the outlet, the pressure difference will decreases soon, and gas rips through. After putting the coal sample processed by the water-based foam into the test tube, the inlet pressure can reach up to about twice as high as the outlet, but it can't last long, so the sealing performance is not obvious. After putting the coal sample processed by the gel foam into the test tube, the inlet pressure can reach up to about 6 times as high as the outlet, and the sealing performance is obvious. We can see from the sealing tests of three different samples that sealing strength of the material of gel foam is highest.

4 GENERAL SITUATION OF WORKING FACE

The 7162 working face of LongDong coal mine has recoverable coal reserves of 576200 t, Working face length of 800 m, slope length is 150 m, coal seam thickness is 5.2 to 6.9 m, the average coal thickness is 5.4 m, coal seam dip angle is 22° to 31°, and the average inclination is 25°. Adopt longwall light fully mechanized sub-level caving mining, a mining caving, low recovery rate, remaining coal of goaf is more. The 7162 roof litho logy is mainly for the fine-grained sandstone and sandstone, belonging to the hard roof, roof first cross step distance is 50 m, showed the cycle pressure, cross step down distance is about 30 m, so as goaf compaction time extended, there is a lot of space porosity and air leakage seriously.

The 7162 coal seam spontaneous combustion in coal seams, with explosion risk, has a low gas level. The geological structure of the face is more complex, roadway excavation revealed 13 faults. F114, F108, as the working face advancing and after the demolition process, the protection pillar will withstand the huge rock pressure, the 5 faults will have a greater impact on protection pillar integrity. Fault at the top of the coal is difficult to put a net retention caused by a large number of coals in goaf. As affected by the F108 fault, the face lower half in the F108 fault at the jumping surface, there is a gap of 2 m. Leave here 45 m pillar, surrounded by the pressure of coal pillar crisp formed float coal accumulation; create conditions of coal spontaneous combustion. The 7162 working face goaf has a high risk of coal spontaneous combustion.

5 APPLICATION EFFECT ANALYSES OF GEL FOAM MATERIALS

According to the field monitoring results of coal temperature and gas concentration, combining with the results of numerical simulation, perfusion gel foam for easy spontaneous combustion area of the 7162 working face in LongDong coal mine. Coal temperature in goaf has been monitored in real-time after perfusion, five measure points has been put along the working face in goaf, as shown in Fig. 5.

Part temperature monitoring results of 7162 fully mechanized face in goaf are shown in Table 4.

Seen from Table 4, the temperature of remaining coal with less than 26 m from the working face rises very slowly, This shows that roof caving rock of this area is in loose accumulation state, the pore is more and larger, air leakage intensity is big, and coal spontaneous combustion will not occur; temperature of remaining coal rises significantly within the scope of 34 m ~ 110 m from the working face, which shows that remaining coal in

this region is oxidation heating as the growth of the time, leading to coal spontaneous combustion. Taken injected gel foam material can effectively prevent the occurrence of spontaneous combustion. The temperature of remaining coal with more than 100 m from the working face begins to reduce slowly, because rock heat dissipation makes oxidation heating gradually disappear, the temperature of remaining coal returns to normal.

6 CONCLUSIONS

1. The gel foam combination of the advantages of gel and three-phase foam has good fire prevention and extinguishing performance.
2. By theoretical analysis and experimental research, selecting sodium laurate and SDS as foaming agent, CMC as form-stabilizing agent, AM as gelling agent, an MBA as the cross-linking agent.
3. The optimum formula for gel foam materials by experimental study is: foaming agent compound with sodium laureate and SDS at the ratio of 2:3, concentration for 0.6%; foam-stabilizing agent CMC concentration for 0.1%; gelling agent AM concentration for 0.3%; cross-linking agent MBA concentration for 0.3%. The gel foam materials have excellent inhibitor performance and sealing performance for the spontaneous combustion prevention.
4. The gel foam materials were grouted to goaf of 7162 working face in LongDong coal mine for fire prevention and extinguishing. The results in monitoring sites show that the gel foam materials had effectively restrained spontaneous combustion in goaf, and guaranteed the safety mining.

The research on water inrush from overburden and early warning technology according to electrical characteristics in Qidong mine

Yunhai Zhang
Wanbei Coal Power Group Company, Suzhou, China

Hao Huang
North China University of Science and Technology, Beijing, China

ABSTRACT: The water hazards from overburden seriously threatened the mining safety in Qidong coal mine and the early warning technology to prevent the disaster become an urgent problem to solved. Electrical prospecting theory illustrates that before the water inrushes from the overburden aquifers into coal mine, the geoelectric characteristics of overburden strata will change. In combination with hydrological observation online system, monitoring and analyzing the electric field through the network parallel electrical method successfully predicted water inrush from roof aquifers in the working face 7130 and the losses were avoided. The tests found that the apparent resistivity and the potential changes simultaneously with the water levels in boreholes and 20 ~ 30 m ahead of water inflow. This provides a reliable practical significance for the early warning of roof water inrush.

1 INTRODUCTION

Due to complicated hydrogeological conditions, the Qidong coal mine has occurred many water hazardsfron the overburden aquifers. Such as, the water in rush from the No. 4 pore aquifer in the working face 3222 in 2001. On September 16, 2002, a heaver water hazard with max flow of 227 m^3/h happened again in the working face 3221. As the two strong aquifers --pore aquifer and sandstone aquifer in the overburden exists, mining activities is always in the dangerous conditions.

Water disaster from alluvium aquifers is a common form in both Lianghuai coal field and west Shangdong coal field. This cases over six billion tons of coal reserves unminable. Therefore monitoring roof water disaster harbingers and making early warning are significant to release the coal reserves, ensure the production safety in Lianghuai and Western Shangdong coal mines areas.

Experts and scholars have done a lot of research work in our country and put forward a series of theoretical methods. In terms of mechanism of roof water inrush, Liu Tianquan proposed overburden failuredoctrine, according to the overburden deformation characteristics and water conductivity overburden can be divided into "three zones". Professor Gao Yanfa proposed "four band" model for rock movement. Ming-Gao Qian has proposed "Masonry beam" mechanical model and "key strata theory", SONG Zhen Qi supposed mining pressure in the overburden as "passing rock beams" (Miao 2004, Zhang 2008, Wang 2007), Wang Jingming (Wang & Yu 2010) proposed a new type hazards due to "strata separation water " and its treatment method.

In terms of roof water disasters forecasting warning, Wu Qiang forward "three figures—double indexes "to predict roof water inrush disasters quantitatively; Many scholars introduce the numerical simulation technology for safety evaluation and zoning. Since roof water inrush involves multiple factors, the traditional warning technology is constricted due to a single factor analyses (Wu & Wang 2007, Chen & Liu 2010).

The parallel electrical tests in Qidong Coal Mine achieved good results, and early warning of schedule comply with the design requirements. This technology for under the threat of "the fourth aquifer" in Lianghuai mining areas have promotion value.

2 ROOF WATER INRUSH EARLY-WARNING MECHANISM BASED ON ELECTRIC FIELD

Sandstone water inrushes into the mine along the roof collapse caused fissures electrical changes ahead is the foundation of electrical method early warning.

In process of coal mining, the overburden lose support, the original stress state changes, roof strata movement, deformation even aving. If the cracks spread achiveaquifer, which above roof and it is likely to become into underground aquifer water channel. Actually, in the process of overburden caving with collapse Angle existing, the farther at the top of the rock burst or bending deformation, the more advanced (fig. 2–1). At the same time, damage or deformation of rock permeability coefficient has changed (Wang & Dong 2005), as shown in figure 2–2.

The figure shows that the stope shear stress contours and permeability coefficient are extended forward at the top, which will cause an increase in overburden and overburden fracture water level changes, which will become sign of water hazard warning.

Besides changes in mechanical properties of rock, the electrical significant changes of destroyed rock will occur. When rock under high natural stress state, due to the pressure, the solid particle land area will increase, the resistivity value decreased; When stress more than rock mass itself strength, rock mass rupture, the resistivity value will rise. According to field exploration theory, rock resistivity values determine apparent resistivity values

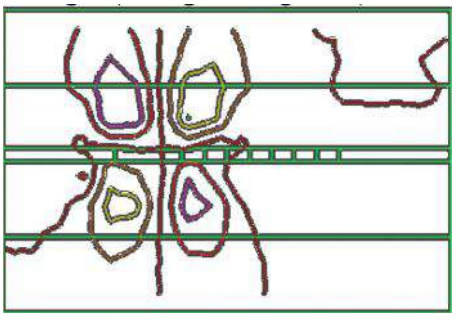

Figure 1. Stope surrounding shear stress contours map.

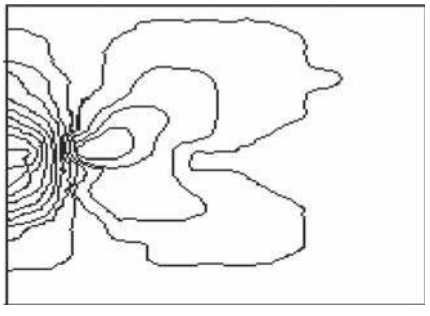

Figure 2. Incremental permeability coefficient contour map.

change, though the apparent resistivity prospecting methods to discovery stress state and deformation and failur of rock mass. If the damage zone does not contain water, the resistivity values will rise, the amplitude more greater, the destruction more completer; if damage zone filled with water, within resistivity values of the damage zone will be significantly reduced.

Groundwater during exercise interact with media various in rock, in the solid, liquid medium generate the electric field exception, the use of natural electric field anomaly in geotechnical engineering seepage studies have actually been applied. The indoor transient response experimental study, which combine earth's natural electric field with the person workshops shaw that (Liu, et al. 2009): Water seepage resulting resistivity significantly lower and supply current significantly increased; The potential of natural electric field and primary field is far higher than that of water-filled the potential of the medium, the position; as time goes by, the electrode potential and the power supply current is increased. Through monitoring of ground electric field can be visually the change of rich water condition of medium, the seepage velocity, seepage saturation state, etc. Therefore, water seepage caused the ground electric field anomalies, through to the electric field anomalies inversion groundwater seepage process inevitably, so as to achieve early warning of roof water disasters.

3 PRINCIPLES OF PARALLEL ELECTRICAL WARNING

Parallel electrical technology is a real-time field observation technology, which is characterized at the same time of the power supply, continuous measurement of all measured electrode potential duration curve, obtained through the excitation current and the potential of space-time curve can decompile a natural field for arbitrary electrode, primary field, the response of the secondary field potentials (Figure 3-1), At the same time, according to the electrode combination of three-dimensional coordinates, Complete three-dimensional calculation of apparent resistivity conventional.

Three-dimensional arrangement of electrical observations in Figure3–2 shows, designing 1 to 47 electrodes are arranged in order, through the electrode loop and synchronous parallel measurement of power form the whole space included roadway current line distribution. 1,6, the 12th electrode is formed when the space current power line distribution. Parallel electrical work is divided into AM and ABM method: AM method powered electrode when working from the 1st cycle to 47 electrodes,

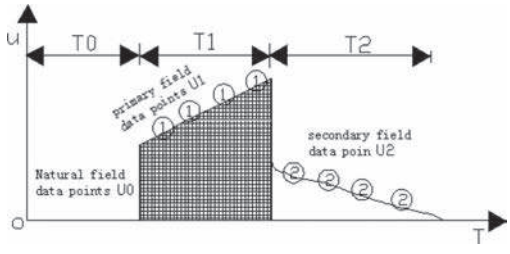

Figure 3. Response potential.

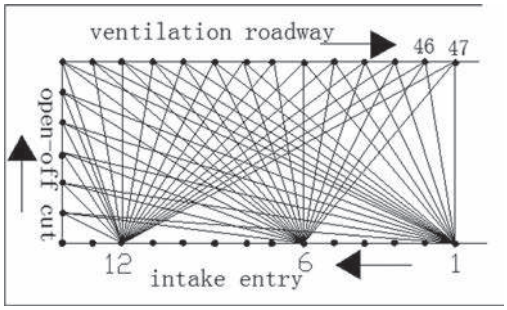

Figure 4. The three-dimensional electrical method electrode layout and the current line.

parallel acquisition and other measuring electrode common reference electrode potential difference; ABM method of operation, the electrodes 1 to 47 sequentially assume A, B power supply, the other measuring electrode parallel acquisition difference potential of the reference electrode and the common, measurement electrode is not idle.

4 PRACTICAL APPLICATION

4.1 *Working face overview*

Qidong Coal Mine coal working face 7_1 30 is located in 3th mining area in the east wing of mine field, under great threat of fourth aquifer (the fourth aquifer) of unconsolidated aquifers. The working face orientation is 355 °~35 °, dip is 11°~14 °. The main roof is light gray, sandstone, average 14.4 m; Immediate roof is a dark gray mud rock, the average thickness 1.7 m. In accordance with on-site geological analysis, the II blocks has a large risk to the production of working face. Combined with the actual monitoring work mainly analyzed the block, (Fig 5).

The fourth aquifer total thickness of the working face $7_1$30 Roof about 3.7~38. 21 m, lithology particle coarsening of the sand and clayey sand, there are also gravel and gravel. High crack detection drill field results show that after working face advancing 30 m seam mining "two band" basically

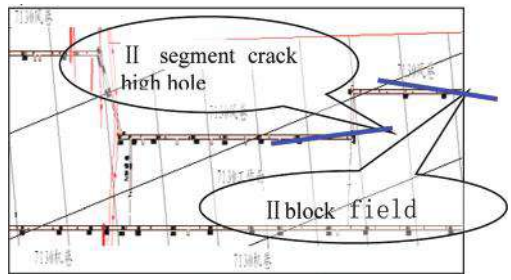

Figure 5. Working face 7130 layout and engineering overview map.

formed in the region. In the top plate 14.75 m of 7_1 coal formed capcaving zone ceiling, Fractured height is 40 mat the top, mining thickness calculated in accordance with 3 m, caving ratio of 4.55, split-production ratio of 13.4. This indicates that Working face $7_1$30 Mining overburden rock fissures height likely to achieve "the fourth aquifer" bottom border, may become water channel guide of the "the fourth aquifer", threatening the safety of mining working face.

4.2 *Early warning project arrangement*

The arrangement form used in the electrode cables buried inside seam roof, electrical meter installed in the tunnel behind, linked ground monitoring station through the underground cable.

II blocks arranged toward the plane of the roof drilling. Field observation wells are arranged along the direction of Wind Tunnel Working face, At the front 14 m lane S18 measurement points are arranged drill field. Drill1 where in the holes arranged 48 electrodes, the electrode spacing of 2 m, 32 electrodesare arranged in the hole2, an electrode spacing of 3 m.

4.3 *Analysis*

1 Natural potential changes

Working face 7130 segment roof crack high detection hole data suggest that two drilling natural potential fluctuation has positive correlation with block period of water yield of working face 7130. the natural potential in drilling increases, the water amount of working face increases (Figure 7), which is mainly due to the high crack deflection drilling work within all things, drilling electrode direct contact with roof water, the natural potential changes in direct response to the changes of the water.

2. Related changes of excitation current

Figure 8 shows the excitation current in the event of an increasing trend after the working face amount

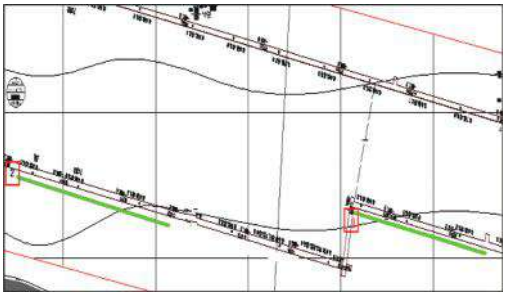

Figure 6. Working fac 7130 roadway monitoring system electrical schematic plan view layout.

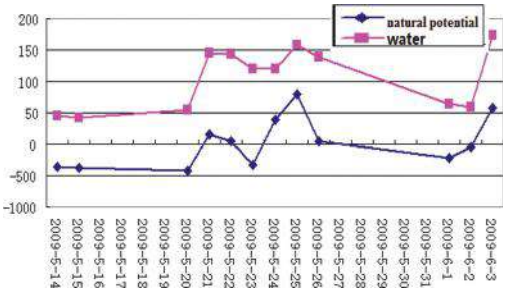

Figure 7. Working face 7130 block water borehole drilling natural potential and dynamic curve.

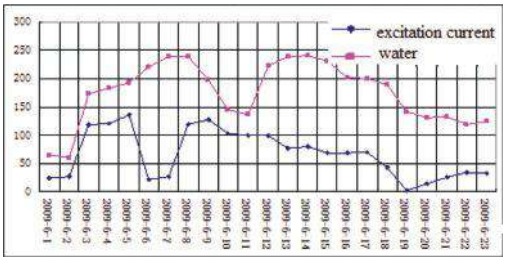

Figure 8. Working face 7130 II Stage #17 electrode excitation current related water figure (current: mA).

of water in the next 2 to 3 days or less appeared an increasing trend, when the excitation current is reduced, working face out of water also decreased slightly. Because drilling electrode arrangement on the roof, when roof water after drilling electrode, electrode exciting current to increase drilling, but this roof seepage water is not the working face, so you can predict the future of working face water 2~4 days there will be a larger increase.

Compareing excitation current curve and the curve of water, it shows that the excitation current rise rate change point corresponds to the future of water rise. Observational data found that S_I that

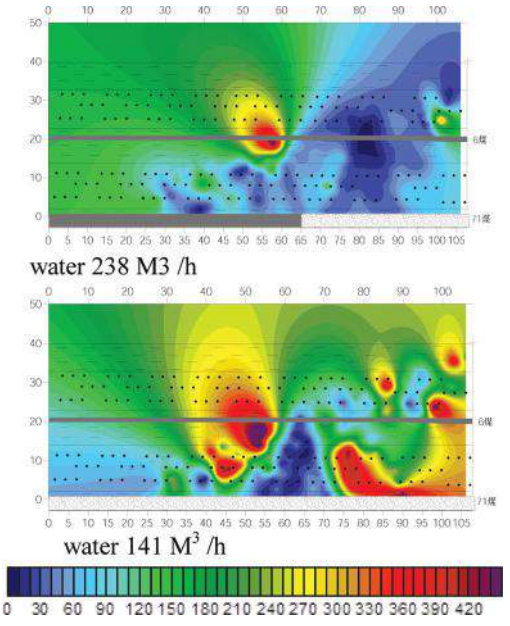

Figure 9. Working face 7130 stage apparent resistivity change map.

the excitation current rate of rise is 3.5 mA / h was water inrush predictors, the higher the rate of rise, indicating that the larger water.

3. Changes of resistivity

Because the roof water seepage areas generally are a relatively low resistance area, by the monitoring results show that the low resistance detection area of the roof area has a certain change in the process of mining face. When the low resistance region developed up and down, the amount of water in working face increases (Figure 8 Left figure), when the low resistance region narrow, and the probe resistivity overall tended to increase, the working face water has decreased (Figure 8 Right figure). Through this period the roof monitoring activities indicate that inthe detection area less than 25Ω · m below of the low resistance region are roof water seepage area, By analyzing low resistance region changes in the spatial morphology and characteristics, which possess the roof water seepage regional space distribution characteristics.

5 CONCLUSIONS

According to mining theory, when roof collapse caused by mining communication with fractured porous and fractured aquifers caused when water

seepage along the damage zone, thus forming the roof water damage. In the percolation process, the natural potential, the excitation current and the apparent resistivity and other parameters of the geoelectric field will produce spatial transient response. Therefore, by inversion of geoelectric field anomaly floor water damage can be predicted. By the study of Qidong Coal Working face 7130, it can be found that:

1. The location of groundwater seepage through natural potential rise, with advanced sensing capabilities. Natural potential increase in the time direction airspace consistent with the seepage flow. Natural potential isochron indicating extreme points seepage locations.
2. Excitation current degree of water saturation of the aquifer is sensitive, after the excitation current in the event of an increasing trend the working face amount of water in the next 2 to 3 days or less appeared an increasing trend, when the excitation current is reduced, working face out of water is also slightly reduced.
3. Resistivity exploration analysis result is helpful to water seepage from roof area of space positioning, the morphological changes of the low resistivity zone corresponds to roof water seepage regional variation. By analyzing the low resistance region's development, the evolution of morphology, we can determine the seepage area development and change, at the same time forecasts the location of the future effluent preliminary.

ABSTRACT: In order to solve the problem of gas control in high gas coal face, gob-side entry retaining technology was implemented to achieve Y-shaped ventilation. Based on the working-face 18205 in Tunlan Mine, aiming at the force condition of different width of roadway-side filling body under the second mining influence, numerical simulation analysis was done, combining with field practice, and the conclusion was that the reasonable width of filling body was 2.5 m. Force analysis inside it showed that shear failure occurred. The both inside and outside reinforcement measure was adopted, installing bolting with net outside the filling body and steel fabric inside the filling body, and the gaps in the filling body were sealed by guniting. Gas comprehensive control technologies were put forward including gas drainage by buried pipes in filling body and inclined bed plate tunnel. Field observations showed that the pressure of gob-side entry retaining was steady and the treating effect of gas was remarkable, achieving great economic and security benefits.

Xishan Coal Electricity Group Company is a coking coal production base in China, the mining of coal seam exploitation takes medium-thick seam and thin seam as the principal thing. The company-owned Tunlan Mine is a high gas mine. Such as the relative gas emission rate of No.8 coal seam is 8.63~15.49 m^3/t, gas pressure is 1.9 MPa, working faces exploit at the same time, drivage-mining link is tense. The entry protection coal-pillar is generally 20 m between sections, and the coal face reserves tail roadway of gas, leading to the low recovery rate of coal resources and the difficulty of gas control. According to the specific conditions of Tunlan Mine, the technology for gob-side entry retaining adapted to the Tunlan Mine was discussed, realizing the Y type ventilation. The application value of it is very important for solving the gas governance problems, improving resource recovery rate, relieving the tension of drivage-mining link, achieving safety, high efficiency and sustainable development of mine.

1 GENERAL SITUATION OF WORKING-FACE

Working-face 18205 of Tunlan Mine is a gob-side entry retaining face, mainly exploiting No.8 coal seam. The average coal thickness is 3.29 m, the dip angle of coal seam is 4 °~6 °, main roof of coal seam is siltstone which is 4.21 m, immediate roof of coal seam is limestone which is 2.42 m, immediate floor is mudstone whose thickness is between 0 m and 1.2 m, the main baseboard is medium-sandstone which is 2.08 m. The trend length of coal face is 1592 m, and the inclined length is 211 m. Two lane roadways and a borrowed one, paralleling to each other, realized the Y type ventilation. The orbital gateway is a gob-side entry retaining roadway, which is rectangular cross-section, 3.5 m high and 5.5 m wide, and the plane of fracture is 19.25 m^2, supported by anchor with network. The layout of roadway pattern is shown in figure 1.

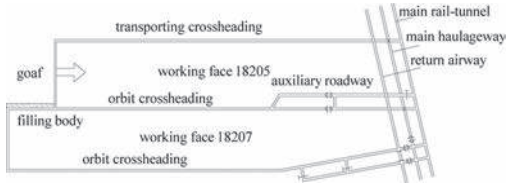

Figure 1. Roadway layout in gob-side entry retaining working-face.

2 STRESS ANALYSIS AND REINFORCEMENT OF ROADWAY-SIDE FILLING BODY

2.1 *The determination of the width of roadway-side filling body*

Roadway-side filling body is arranged between worked out section and orbital crossheading. In order to determine the reasonable width of the filling body, the numerical simulation software FLAC^{3D} conducted stress analysis of filling body whose width is 2.0 m, 2.5 m and 3.0 m, under the second mining influence (Shi & Shi 2012, Chen et al. 2012), according to geological conditions of mining.

From the size of bearing pressure and the damage area of the 2.0 m, 2.5 m and 3.0 m wide filling body in front of the coal face by 30 m, 60 m and 90 m, we could know that, three kinds of filling body under the front abutment pressure were mainly not damaged, and all can meet the requirements of gob-side entry retaining. The front support pressure of the 2.0 m wide filling body is relatively large, and the requirement of the filling material strength will be relatively high. When the width of filling body is 3.0 m, each filling step's filling slurry requirement increases, which will increase the cost, and according to the current conditions of Tunlan Mine, the filling time will take more half an hour than before. When the width of the filling body is 2.5 m, the demand for filling body strength and the actual filling workload are more reasonable. Therefore, the width of the filling body is 2.5 m. Further theoretical analysis of stress distribution for this wide filling body was conducted.

2.2 *Internal force analysis of roadway-side filling body*

The roadway-side filling body was poured integrally by pasty concrete material, each filling's length is 2.4 m and width is 2.5 m. The width of filling body in mined-out area and the orbital crossheading is 1.6 m and 0.9 m respectively. Concrete is a kind of solid which has a lot of micro fractures, and its damage process is the development process of cracks. Concrete is a kind of heterogeneous material, and stress concentration often occurs on the combined surface of the aggregate and mortar, which is the main reason of concrete cracking. The experimental study of concrete strength failure criteria shows that, concrete materials mainly have two damage forms, tensile and shear, and Chinese scholars have derived the expression for calculating the shear strength which is suitable for the concrete (Li & Liu 1993), as follows:

$$\frac{\tau}{f_c}=\frac{1}{K+1}\sqrt{1+(K-1)\frac{\sigma_x}{f_c}-K\left(\frac{\sigma_x}{f_c}\right)^2} \tag{1}$$

$$K=\left(\sqrt{1+\tan^2\varphi}+\tan\varphi\right)^2=\frac{1}{2}\frac{f_c}{f_t} \tag{2}$$

$$\tan\varphi=\frac{\sqrt{2}}{4}\cdot\frac{(f_c-2f_t)}{\sqrt{f_c f_t}} \tag{3}$$

where, f_c = uniaxial compressive strength of concrete; f_t = uniaxial tensile strength of concrete; f = internal friction angle of material.

Substituting the related parameters of the filling material and the stress distribution of filling body under the second mining into the expression of shear strength calculation of concrete, the shear stress of filling body is 5.2 MPa, but the maximum shear stress of concrete is 3.7 MPa through the experimental analysis, and shear failure would occur inside the filling body. Therefore, the filling body should be reinforced to increase its strength and play the support efficiency.

2.3 *The reinforcement of filling body*

2.3.1 *The inside reinforcement of filling body*

In order to increase the strength of the filling body, 5 pieces of steel mesh were placed in, realizing the reinforcement of the filling body (Yang et al. 1999). Steel mesh specifications are length (2250 mm) and height (3000 mm), using the steel bar of 8 mm diameter, and the steel mesh grid size is 150 mm and 150 mm. ①There were three pieces of steel mesh perpendicular to the orbital crossheading's two sides and floor, and they were linked with a deformed bar, whose diameter was 16 mm and length was 2100 mm. ②Two pieces of steel mesh were placed parallel to both sides of the orbital crossheading, and connected by the wire as a whole with the previous three pieces of steel mesh.

2.3.2 *The outside reinforcement of filling body*

On the surface of filling wall, three rows of Φ14 type bracket, length 2.6 m, with four holes were arranged along the roadway. Every two brackets interconnected mutually, and the steel mesh of No.8 and left-handed special thread steel anchors ranked IV which was super strength pre-tension formed the combination support. Diamond metal net was adopted on the uneven filling wall. The anchors' specification was Φ20-M22-1600 mm. Each anchor was extended and anchored by the medium speed resin cartridge of Z2355; the interrow spacing is 900 mm × 800 mm (Li et al. 2011). On the basis of anchor joint reinforcement of steel strip and bar-mat reinforcement, in order to prevent the surrounding rock from weathering, 50 mm thickness concrete was jetted to seal the surface of filling body.

Due to the roof and floor of the roadway were not flat and the float coal of bottom board was not clear in time, or the influence of the filling process, the filling body contacted leaky and stressed unevenly, creating gaps. In order to prevent the leakage of gas, the gaps should be sealed by guniting.

3 THE TECHNICAL MEASURES OF GAS COMPREHENSIVE CONTROL

The working face uses gob-side entry retaining technology, realizing Y type ventilation of two downcast airways and one return air course, which means that the transporting crossheading is the main downcast airway and the orbit crossheading is the auxiliary downcast airway, retaining the entry to return air. The single coal seam gas drainage methods could not meet the production requirements according to the practice of coal seam gas drainage technology of Tunlan Mine in recent years. The extraction system in working-face 18205 used ground extraction pump downhole movable extraction pump and burying pipes in filling body to jointly drainage gas in coal seam and adjacent layer. The reasonable drainage drilling parameters was determined according to the theory of ground stress, gas geology and rock movement (Chen et al. 2012). The gas emission of the working-face 18205 has greatly improved than the working-face 18203, since using Y type ventilation. But it made bottom gas relatively high, leading to bubbling phenomena, sometimes causing gas transfinite accident, and bringing difficulty to the gas control. Only by increasing air flow rate, the bottom gas has not been fundamentally improved, and the main fan negative pressure would increase and the effect was poor. In order to solve this problem, inclined bed plate tunnel drainage gas technology was adopted in the working-face 18205.

4 FIELD MEASUREMENT OF LANE SIDE FILLING BODY STRESS AND ANALYSIS OF GAS CONTROL EFFECT

4.1 *Filling body stress observation project*

The stress observation of gob-side entry retaining filling body provides the science evaluation basis for the inspection filling effect. According to the mechanical principle and the actual situation of the underground pressure in Tunlan Mine, at the distance of 10 m to open-off cut, 5 points, each interval to 10 m, and another 5 points, each interval to 50 m, were decorated. Two hydraulic pillows were arranged in each observation point of filling body. The height from hydraulic pillow to the floor was 1.75 m and to the both sides of the filling body edge was 1 m. The total observation distance was 300 m.

4.2 *Actual measurement analysis of filling body*

In accordance with stress observation project of the filling body, the stress of it under the second mining influence was observed. The filling body's force was 2~4 MPa and the load anchor's force was 5~25 MPa, which explained that the filling body stress was poor under the second mining influence. Combining with the two sides' displacement of gob-side entry retaining, roof abscission layer observations, the whole pressure of gob-side entry appeared stable, and the width of 2.5 m could satisfy the production requirement.

4.3 *Analysis of gas control effect*

Fully mechanized mining working-face 18205 used Y type ventilation system and gas comprehensive control technology of burying pipes in filling body and inclined bed plate tunnel. Gas extraction effect was obvious. The gas emission from working-face 18205 during mining significantly reduced compared with already picked working-face 18203. The average gas emission of working-face 18203 was 54 m^3/min, and the maximum was 83 m^3/min, while the average gas emission of working-face 18205 was 24 m^3/min, and the maximum was 34 m^3/min. The working-face 18205 gas emission during mining gradually reduced after stoping 850 m, with the bed plate tunnel drainage system forming. The average gas emission was 20 m^3/min and reduced 4 m^3/min than before. This technical measure reduced the concentration of gas and achieved a very good extraction effect.

5 CONCLUSIONS

According to the stress numerical simulation analysis and field production practice of 2.0 m, 2.5 m, 3.0 m wide gob-side entry retaining filling bodies under the influence of second mining, the reasonable width was 2.5 m. The reinforcement measures, as field observations shown, that the anchor belt net was arranged inside the filling body and steel mesh was arranged outside the filling body, could prevent generating shear failure in the filling body, enhance its strength, exert its support performance, and make the gob-side entry retaining mine pressure appear stable.

Gob-side entry retaining working face realized Y type ventilation system. Gas comprehensive control technology, burying pipes in filling body and inclined bed plate tunnel, improved the gas

extraction rate greatly and reduced the working face gas emission, and solved gas overrun problem of the gas coal face effectively, achieving good economic and security benefits.

ABSTRACT: When the working face advancing to the fractured zone, it often encounters the fractured roof in coal mining, which poses a serious safety hazard to underground construction. However, fractured roofs caused by geological structures such as faults, folds and gob area support pressure effects are often encountered in underground mining. Employing the method of strengthening the roof support to control the surrounding rock can hardly achieve the desired security, especially for the fractured roofs happened in gateway, which is likely to cause material waste and limited supporting effect. Therefore, the paper combines fractured roadway surrounding rocks support pressure distribution, starting the change of the nature of the surrounding rock, by injecting Malisan to change the fractured state of the surrounding rock, so as to achieve effective control of the surrounding rock fractured effect.

Keywords: fractured zone, surrounding rock control, grouting reinforcement, roof

1 INTRODUCTION

Coal roof fracturing is one of the hazards of the coal mine production safety. Every year, roof-fall accident caused great casualties, so exploring ways to strengthen the control of gateway roof to help to reduce such safety accidents is worth to study. The roof control of face can be achieved by changing the mining process to strengthen the roof control of hydraulic support, while the supporting effect of strengthening roof support to control fractured roof is limited in both roadways of gateway. A coal mine located in Jinin city, Shandong province employs the method of injection Malisan to change the fractured state of the surrounding rock, to change the block surrounding rock into surrounding rocks of continuity, solidity and integrity, so as to effectively control the surrounding rock fractured state and ensure the coal mine production safety.

2 FRACTURED ROADWAY SURROUNDING ROCKS SUPPORT PRESSURE DISTRIBUTION

On one hand the roadway surrounding rock fracturing is caused by the geological structure, on the other hand, it is caused by support pressure due to mining. Support pressure is generated in the island face, of which the support pressure distribution is similar to the shape of a saddle. By the superposition of mining support pressure and distribution support pressure, it forms a strong concentration of support pressure in the roof coal in the both sides of face. With advancing of the face, this area continues to move forward, and the surrounding of main roof has varying degrees of fractures when the face advancing. The time of main roof collapse in both sides of face is not merely affected by dynamic load, but also by the impact of other factors such as suspending area of main roof in both sides of the mined area and crushed extent of remaining coal pillars, because the badly fracture with burstiness is easier to induce roof accident.

The support of gateway fracture section often employs single hydraulic prop, or building sheds, bolt-mesh-anchors, and cribs. However, those supporting method only controls from external causes, of which supporting effect is limited, wastes a lot of support material, and cannot guarantee the ideal control effect. Therefore, a good supporting effect can be achieved by changing the nature of the surrounding rock to control the roadway deformation and roof fracture.

Affected by support pressure, roadway roof is fractured, it is feasible to employ the method of grouting reinforcement to change the fractured state of surrounding rock (Ge 1996, Yang et al. 1997). Employ Malisan N of Yanzhou Haokeweibo

Mining Engineering Co., Ltd. as the chemical material to reinforce surrounding rock, and respectively apply injection reinforcement to roadway both sides, roof and PVIs, depending on different parameters at different circumstances. In the initial stage of face rib spalling and roof falling, using Malisan material to reinforce or Rockxiu to fill.

3 MALISAN N PERFORMANCES

Malisan N has a high degree of adhesion and good mechanical properties, which can highly adhered with the strata, and its good flexibility and toughness can ensure it withstand the subsequent ground movement, which can maintain the same life span with the face. When the production is injected into the strata, low viscosity mixture is maintained for a few seconds, then penetrates into small cracks and expands, thus effectively strengthening and sealing the processed region. Details are shown in Table 1. Its resin and catalyst for two-component material are in a leading position in the world and have a history of 40 years.

The application scope of Malisan N: cracks and unstable strata reinforcement, water inlet and strata seal, rock reinforcement, and rock rivet seal.

4 MALISAN N REINFORCEMENT PROGRAM

Affected by fault F2 geological structure, rocks within the scope of 50 m near 1311 mining face belt roadway fault F2 outburst, and the coal fractured has lost its integrity and continuity. When the face advancing to the position of fault, roof accident is easily induced, thus resulting in stop production and affecting face advancing. By the mine feasibility studies, chemical material reinforcement roadway processing is implemented in the 1311 face belt roadway structure developed zone and partial fracture zone. Employ Malisan N reinforcement material, and the specific methods are as follows (Chu 2007, Gao 2005):

Table 1. Malisan N technical data.

Project		Resins	Catalysts
Basic ingredients	Density at 25℃(g/cm3)	1.04	1.23
	Viscosity at 25℃(MPa•s)	200	210
	Mixing ratio(Volume ratio)	1	1
	Storage period at 25℃(months)	6	6
	Storage Temperature (℃)	5-30	5-30
	Package	25kg Plastic bucket	30kg Plastic bucket
Polymerization products	Application temperature (℃)	15	25
	The initial viscosity (MPa • s)	450	250
	Start of the reaction (minutes)	1:15	0:45
	The foam time (minutes)	2:10	1:25
	Expansion ratio	2	2
	Pressure(MPa)	>10	>10
	Adhesive strength (MPa)	>1	>1

(1) According to the site examination, drill pores in roadway vault fracture section using pneumatic drill or Roof bolter, pore size is Φ42 mm-Φ45 mm, pore depth is 3 m, row distance is 3 m, grout after pore finished. And then drill pores in roadway vault angle, pore size is Φ42 mm-Φ45 mm, pore depth is 4 m, spacing is 2 m, row distance is 3 m, grout after pore finished.

According to the roadway fracture condition, for example of 5 m coal pillar, drilling with coal electric drill is suggested. Pore size is Φ42 mm-Φ45 mm, pore depth is 2.5 m, spacing is 2 m, and row distance is 3 m, triangular configuration. Put the sealing in the position of 1.5 m and start grouting.

(2) According to site condition, if the first pore grouting volume is controlled in approximately 4 barrels of material, which reflects that this roof is quite fractured and cracks are developed.. If the Malisan material cannot be injected into the cracks, which reflects that the cracks are not developed. The grouting volume is determined by site conditions. Grouting can be guaranteed according to the site condition, the first cycle grout four pores, then view the grouting and effects. The reinforcement length is approximately set as 117 m.

5 MALISAN GROUTING PROCESS

Specific process is shown as Figure 1.

6 MALISAN GROUTING PROCESS

Malisan N dosage can be expected based on the coal volume in designed grouting reinforced region. Specific calculation is shown as formula (1):

$$Q = VrC \tag{1}$$

In the formula:
- Q – designed Malisan N dosage, t;
- V – volume of grouting reinforced region (see formula (2) below), m^3;
- R – density of the coal, $r = 1.4$ t/m^3;
- C – amount of Malisan N grouting in per ton of coal, 0.5%;

$$V = (\pi(R^2 - r^2)/2 + AB - ab) \times L / \sin\delta \tag{2}$$

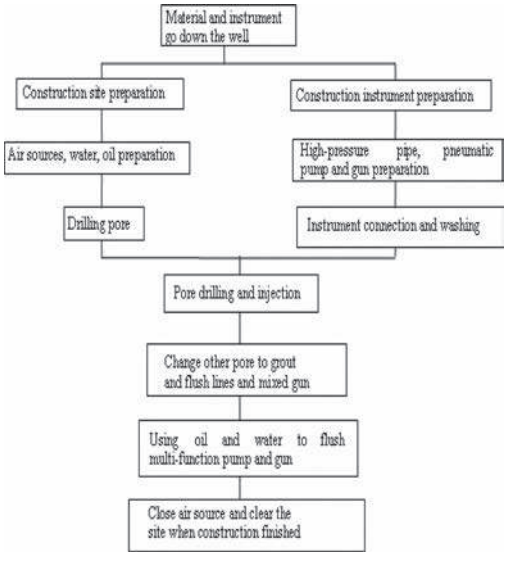

Figure 1. Malisan Grouting Process.

Among them:

R,r – the inner and outer radius of grouting reinforced region, $R = 4.45$ m, $r = 2.06$ m;

A,a – width of grouting reinforced region and non- reinforced region in roadway sides, $A = 7.6$ m, $a = 3.6$ m

B,b – height of roadway, $B = 1$ m, $b = 1$ m

L – coal seam thickness, $L = 3.03$ m;

δ – angle of coal seam, $\delta = 10°$.

Put each parameter into the formula, and calculate $Q = 3.5$ t., the dosage of Malisan N is 3.5 t. Malisan N resin and catalyst mixture ratio is shown as: volume ratio is 1:1, mass ratio is 1:1.17.

7 MINING CONTRAST UNDER SIMILAR CONDITIONS

1305 face and 1311 face are in the same mining area, with similar geological conditions, and both encountered faults in roadways. Because no corresponding roof reinforcement measures were implemented when 1305 face advances cross the fault, head face roof collapse is induced when 1305 face advances cross the fault, which causes great difficulty in safety production, and wastes large amount of materials in roof and buttock control. The material inputs are shown as Table 2.

The total cost of materials is 35983.75 yuan, and raw coal output influence by crossing fault is 5990 t.

Similarly, when 1311 face haulage roadway advances across the fault, Malisan injection is implemented to reinforce the roof, put Malisan 3.5 tons, the unit price is 10,000 yuan per ton, the total investment is 35,000 yuan. No coal wall spalling happens when crossing fault, and no face roof-fall accident is caused, which not only ensures safety production, but achieves economic benefit.

Table 2. Materials cost schedule due to face roof and buttock fracture support.

Material name and specifications	Quantity	Unit price	Total Price yuan
Semicircle wood 1.8×1.5m	498block 12.7m^3	796.46yuan/m^3	10115.04
Semicircle wood 1.8×2.5m	168block 7.2m^3	796.46yuan/m^3	5734.51
Anchoring agent	600strip	2.05yuan/trip	1230
I-steel 2.5m	30strip	79.5yuan/m	2385
Railway 7m	2strip	399.6yuan/strip	799.2
Shearer pick	60bunch	106yuan/bunch	6360
Face anchor (with bedding and cap)	480 strip	17yuan/ suit	8160
Wooden anchor plate	300piece	4yuan/ piece	1200

8 CONCLUSIONS

Employing Malisan N as reinforcement material can ensure no spalling or roof-fall happens in 1311 mining gateway development zone and partial section, which enhances coal carriage capacity. Through the reinforcement of roadway surrounding rock can strengthen the integrity of roadway surrounding rock and improve the overall carriage capacity of the surrounding rock, thereby eliminating the security risks of roadway roof fracture.

Through injecting Malisan N to change the nature of the surrounding rock can achieve the purpose of control of surrounding rock, which not only reduces the waste materials of roadway reinforcement support, but achieves good control, high security and low cost.

ABSTRACT: In order to improve the detection rate of new intruders in coal mine disaster warning internet of things, a new method of Intrusion Detection System (IDS) based on immune algorithm and Back Propagation Neural Network (BPNN) is developed in the paper, on the base of analysis on the network data. In this method, Immune Algorithm (IA) is used to preprocess the network data, extract key features and reduce dimensions of network data set by feature analysis, then BPNN is adopted to classify the data (program) and recognize intruders. Experimental results show that the method is feasible and efficient, and the detection right rate of intruders in internet of things was above 97%.

Keywords: Intrusion Detection System (IDS); Feature selection, Immunity Algorithm (IA), Back Propagation Neural Network (BPNN)

1 INTRODUCTION

The Internet of things is an important part of the new generation of information technology. The Internet of things is an internet of the connection of objects. The dynamic safety early warning system of the coal mine disaster base on the internet of things is a new method and new means to protect the mine safety and is a complicated system project integrated with the coal mine safety theory internet of thing technology and the early warning technology. The system structure of the dynamic early warning system could be divided into three structures, as a sensing layer, a transmission layer and a application layer and could realize the management of the mine safety information system, the dynamic warning of the Coal Mine disaster, the joint sharing of the safety information, the experts system of the disaster prevention and control and other functions. The dynamic early warning system could integrate the available resources and realize the coordinative management and control of the personnel, machine, equipment and basic infrastructures within the production network under the complicated environment.

The manipulations may take the form of attacks by skilled malicious hackers, or script kiddies using automated tools. Intrusion Detection System (IDS) is used to detect all types of malicious network traffic and computer usage that can't be detected by a conventional firewall. This includes network attacks against vulnerable services, data driven attacks on applications, host based attacks such as privilege escalation, unauthorized logins and access to sensitive files, and malaria (viruses, Trojan horses, and worms).

An IDS is composed of several components: Sensors which generate security events, a Console to monitor events and alerts and control the sensors, and a central Engine that records events clogged by the sensors in a database and uses a system of rules to generate alerts from security events received. An IDS also is a large and complicated project. Now, there are yet many weaknesses in IDS, it should be improved.

IDS includes choosing a set of features, building up a set of attack models or normal models, matching or comparing the models with activation of now executed program, obtaining the difference of the built models and activation of now executed program, and alarming.

An IDS is a large and complicated project. Now, there are yet many weaknesses in IDS, it should be improved (YU, 2009). IDS includes choosing a set of features, building up a set of attack models or normal models, matching or comparing the models with activation of now executed program, obtaining the difference of the built models and activation of now executed program, and alarming.

Currently, how to extract the appropriate features for IDS is less studied. This article will do some research on this issue.

In IDS, to choose a set of features is very important (YU, 2008). If the set of features used in IDS are chosen wrongly, no matter how perfect next later works are, the final results of IDS are wrong. In addition, action classification in IDS is completed through mathematics method, which requires that number of features is small. How to determine a good group of features and how to classify and recognize intruders are important in IDS (Rao & Yang, 2003). The solutions to the problems are provided in the paper. In this paper, Immune Algorithm (IA) is used to preprocess the network data, to determine a good group of features, and the Back Propagation Neural Network (BPNN) is adopted to classify and recognize the intruders. Experimental results show that the method is feasible and efficient. The approach is introduced in follow sections.

2 BACK PROPAGATION NEURAL NETWORK (BPNNN)

In paper, the Back Propagation Neural Network (BPNN) is used to class and recognize intruders and normal programmes. The BPNN abstracts and simulates some basic characters of human brain by mathematical approaches. BPNN is a nonlinear information processing system that simulates the structure and its function of human brain.

The essence of the material that follows is the use of a multitude of elemental nonlinear computing elements (called neurons) organized as networks reminiscent of the way in which neurons are believed to be interconnected in the brain.

The resulting models are referred to by various names, including neural networks, neurocomputers, Parallel Distributed Processing (PDP) models, neuromorphic systems, layered self-adaptive networks, and connectionist models. Here, we use the name neural networks, or neural nets for short. We use these networks as vehicles for adaptively developing the coefficients of decision function via successive presentations of training sets of patterns.

Pitts [1943] proposed neuron models in the form of binary threshold devices and stochastic algorithms involving sudden 0–1 and 1–0 changes of states in neurons as the bases for modeling neural system. Subsequent work by Hebb [1949] was based on mathematical models that attempted to capture the concept of learning by reinforcement or association.

More recent results by Rumelhart, Hinton, and Williams [1986] dealing with the development of new training algorithms for multilayer perceptions have changed matters considerably. Their basic method, often called the generalized delta rule for learning by back propagation provides an effective training method for multilayer machines. Although this training algorithm cannot be shown to converge to a solution in the sense of the analogous proof for the single-layer perception, the generalized delta rule has been used successfully in numerous problems of practical interest. This success has established multilayer perception-like machines as one of the principal models of neural networks currently in use.

2.1 *Perception for two pattern classes*

In its most basic form, the perception learns a linear decision function that dichotomizes two linearly separable training sets. Figure 1 shows schematically the perception model for two pattern classes. The response of this basic device is based on a weighted sum of its inputs; that is,

$$d(x) = \sum_{i=1}^{n} w_i x_i + w_{n+1} \tag{1}$$

which is a linear decision function with respect to the components of the pattern vectors. The coefficients $w_i, i = 1,2,\ldots,n,n+1$, called weights, modify the inputs before they are summed and fed into the threshold element. In this sense, weights are analogous to synapses in the human neural system. The function that maps the output of the summing junction into the final output of the device sometimes is called the activation function.

When $d(x) > 0$ the threshold element causes the output of the perception to be +1, indicating that the pattern x was recognized as belonging to class w_1. The reverse is true when $d(x) < 0$. This mode of

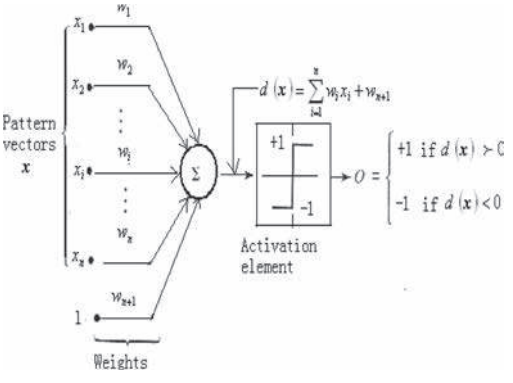

Figure 1. Two equivalent representations of the perception model for two pattern classes..

operation agrees with the comments made earlier in connection with $(d_i(x) - d_j(x) = 0)$ regarding the use of a single decision function for two pattern classes. When $d(x) = 0$, x lies on the decision surface separating the two pattern classes, giving an indeterminate condition. The decision boundary implemented by the perception is obtained by setting Eq. (1) equal to zero:

$$d(x) = \sum_{i=1}^{n} w_i x_i + w_{n+1} = 0 \tag{2}$$

$$w_1 x_1 + w_2 x_2 + \cdots + w_n x_n + w_n = 0 \tag{3}$$

which is the equation of a hyper plane in n-dimensional pattern space. Geo-metrically, the first n coefficients establish the orientation of the hyper plane, whereas the last coefficient w_{n+1} is proportional to the perpendicular distance from the origin to the hyper plane. Thus if $w_{n+1} = 0$, the hyper plane goes through the origin of the pattern space. Similarly, if $w_j = 0$, the hyper plane is parallel to the x_j-axis.

The output of the threshold element in Fig. 1 depends on the sign of $d(x)$. Instead of testing the entire function to determine whether it is positive or negative, we could test the summation part of Eq. (1) against the term w_{n+1}, in which case the output of the system would be

$$O = \begin{cases} +1 & if \sum_{i=1}^{n} w_i x_i \succ -w_{n+1} \\ -1 & if \sum_{i=1}^{n} w_i x_i \prec -w_{n+1} \end{cases} \tag{4}$$

This implementation is equivalent to Fig. 1 and is shown in Fig. 1, the only differences being that the threshold function is displaced by an amount $-w_{n+1}$ and that the constant unit input is no longer present. We return to the equivalence of these two formulations later in this section when we discuss implementation of multilayer neural networks.

Another formulation used frequently is to augment the pattern vectors by appending an additional $(n + 1)$st element, which is always equal to 1, regardless of class membership. That is, an augmented pattern vector y is created from a pattern vector x by letting $y_i = x_i$, i=1,2,…,n, and appending the additional element $y_{n+1} = 1$. Equation (1) then becomes

$$d(y) = \sum_{i=1}^{n+1} w_i y_i = w^T y \tag{5}$$

where $y = (y_1, y_2, \ldots y_n, 1)^T$ is now an augmented pattern vector, and $\boldsymbol{w} = (w_1, w_2, \ldots w_n, w_{n+1})$ is called the weight vector. This expression is usually more convenient in terms of notation. Regardless of the formulation used, however, the key problem is to find $\boldsymbol{w}$ by using a given training set of pattern vectors from each of two classes.

2.2 *Training or learning*

The BPNN is based on the use of sample patterns to estimate statistical parameters of each pattern class. The patterns (of known class membership) used to estimate these parameters usually are called training patterns, and a set of such patterns from each class is called a training set. The process by which a training set is used to obtain decision functions is called learning or training.

The patterns (of known class membership) used to estimate these parameters usually are called training patterns, and a set of such patterns from each class is called a training set. The process by which a training set is used to obtain decision functions is called learning or training.

The training patterns of each class are used to compute the parameters of the decision function of BPNN corresponding to that class. After the parameters in question have been estimated, the structure of the BPNN is fixed, and its eventual performance will depend on how well the actual pattern populations satisfy the underlying statistical assumptions made in the derivation of the classification method being used.

The statistical properties of the pattern classes in a problem often are unknown or cannot be estimated. In practice, such decision-theoretic problems are best handled by methods that yield the required decision functions directly via training. Then, making assumption regarding the underlying probability density functions or other probabilistic information about the pattern classes under consideration is unnecessary.

3 IMMUNITY ALGORITHM

Immunity algorithm work in the same way the biological immunity principle does. According to biological immunity principle, the biology immune system produces automatically the corresponding immune body (antibody) against the antigen through the cell fission and the disintegration, to resist the antigen that invades the life body. This process is called the immunity reply. In the immunity reply process, part of antibodies is preserved as memory cell. When the similar antigen invades the life body once more, the memory cell is activated and produces rapidly the massive immune bodies. This causes that 2nd reply is more intense than the primary reply, which manifests memory function of

the immune system. A kind of immune body and another kind of immune body are also promoted and suppressed mutually, to maintain the multiplicity of the immune body and the balance of immunity. This kind of balance is carries on according to the density mechanism, namely the density of the immune body is higher, the immune body is suppressed more; The density of antibody is lower, the antibody is promoted more. This manifests self-adjustment function of the immune system.

The immunity algorithm is a new method developed recently in the artificial intelligence, which is a new algorithm that is designed under enlightenment of the biology immune system.

In the immunity algorithm, the antigen is corresponding the objective function and variant kind of constraint conditions; and the immune body (antibody) corresponds with the optimal solution. The kissing degree between the antibody and antigen corresponds with the match degree of solution and the objective function.

3.1 *Encoding methods*

In the immunity algorithm, encoding method of the immune body and antigen mainly has three kinds, that is, the binary code, the real number code and the character code, and in minor case, the grey code (gradation) is used, and so on. Binary code has merits of strong search ability, simple crossover and variation operation. Therefore, the binary code method is selected in this article. As to P attributes of the network data, each attribute is expressed by the binary string which is E in the length. The decimal base value in correspondence with this binary value represents the weight value of the attribute. Therefore, each immune body contains $P \times E$ binary code.

3.2 *Methods for computing immune body density*

Immune body density is mainly used to maintain multiplicity of the immune body, and raise the partial search ability. The methods for computing immune body density are mainly ones based on Euclidean space distance and information entropy. The latter is used in this article, to compute immune body density. Information entropy is used in indicating multiplicity of the immune body in the community. The immune body density is computed and obtained by average information entropy of a group of the immune bodies.

3.3 *Method for computing the affinity between immune body and antigen*

The affinity between immune body and antigen is used in indicating the degree in which the immune body recognizes the antigen. In this article, BPNN, which is a classification method, is applied to obtain the rate of alarm missing and the rate of false alarm, then compute the affinity between immune body and antigen.

3.4 *Steps of immunity algorithm*

The immunity algorithm step proposed in this article is as follows:

1. Analysis question: Analysis and understand the characteristic of solution, and design the appropriate coded form of the solution.
2. Initialization: Initialize immune body group as well as memory storehouse (base). Set the initial values of immune body group size n and memory storehouse size m.
3. Evaluate each immune body in the immune body group: Expectation reproduction rate of the immune body is taken as the standard evaluate index of immune body in this algorithm. The index is determined together, according to immune body density and affinity between the immune body and the antigen.
4. Save the superior immune body to memory storehouse (base): The immune bodies are ordered by descent, according to expectation reproduction rate. Save the former m immune bodies with higher expected reproduction rate into memory storehouse (base).
5. Judge whether the stop condition satisfies: Yes, then algorithm stops; otherwise, continues the operation of the next step.
6. Production new community: Based on the fourth step computed result, the selection, crossover and variation operations of each immune body in each immune body group are carried on, to obtain new community, according to its expectation reproduction rate. The new generation of community is constituted of the new community obtained just about and m individuals in the memory storehouse together.
7. Change to the step 3, and continues to carry out.

4 THE INTRUSION DETECTION SYSTEM MODEL BASED ON THE AI-BPNN

The essential idea of BPNN classification is to use a gradient method to modify weights and thresholds of BPNN to make the square sum of error of network output minimum, so that the two classes of data become linearly separable, as far as possible. The pretreatment of the data and features used in IDS is carried on with the immunity algorithm, to withdraw main attribute features related with intrusion detection. The classification of the data

processed is carried on with BPNN. The outline of the concrete IDS model based on the AI-BPNN is: (1) network data set, (2) immunity pretreatment, (3) BPNN training, (4) BPNN sorter, (5) policy-making response (react).

5 EXPERIMENTS AND RESULT ANALYSIS

The data used in the experiment is KDD CUP 99 data sets. This data set provides 9 week's network connection data that gathered from on a simulation local area network. Each record in the data set has contains 41 features and 1 marking of kind. The record in the data set has been divided into 5 kinds, namely normal connection (Normal) denial of service (DoS), the unauthorized remote service to login (R2 L), the unauthorized access to the local super user's privilege, scanning and probing (Probing).

Because primitive data sets of KDD CUP 99 are too huge, in order to carry on the confirmation to the algorithm, the representative data sets had chosen in this article, to product stochastically training set and test set, which have contained 5072 and 5280 records separately. In the practical test, the mean value of 10 test results is taken as the test finishing result. The practical immunity algorithm parameters are as follows:

The community size is 120, alternate number is 50 generations, the memory storehouse size is 7, crossover rate is 0.5, and the variation rate is 0.02.

The BPNN is made of three layers, the first layer is made of 22 nodes, the second layer consists of 25 nodes, and the last layer consists of a node, whose value is 0 for normal users, 1 for the intruder. After the BPNN is trained successfully, that is, its weight and threshold values are selected, the procedures running in the network can be monitored and evaluated with the neural network. Experimental result is as shown in Table 1.

The experimental results show that correct recognition rate is enhanced greatly by method developed in the paper, while the rate of false alarm rises lightly.

Table 1. Comparisons of correct identification rates for intruders in some different IDSs.

Method for IDSs	The rate of alarm missing	Correct recognition rate
BPNN	4.5%	80.2%
Immunity algorithm (IA) + BPNN	4.7%	97.3%

6 CONCLUSION

In data used in Intrusion Detection System (IDS), there are non-correlated or the redundancy features which causes performance of IDS to drop. Other, in data used in IDS, the dimension of features is higher. Thus, the extraction of characteristic was carried on in the paper. Considering the global restraining of immunity algorithm as well as the immune body multiple features, it was proposed to carries on pretreatment of the data and extraction of essential attributes with the immunity algorithm, then classify and recognize intruders with BPNN. IDS model based on the AI-BPNN was established. The experiments indicated that this algorithm was feasible and effective, and the detection right rate of intruders in internet of things was above 97%.

ABSTRACT: Using Forchheimer and non-Darcy seepage theory, revealed the mechanism of water inrush from the structure of nonlinear dynamics system instability perspective. Research shows that: Mine water inrush is related to the porosity of rock, particle diameter, mechanical properties of penetrating liquid, and the velocity of flow etc. The smaller of porosity and particle diameter, the larger of Reynolds number for causing loss of stability of seepage, i.e. the steady state is not easy to lose; otherwise, the larger porosity and particle diameter, the smaller of Reynolds number for causing loss of stability of seepage, the steady state is easy to lose.

1 INTRODUCTION

Broken rock of mining is caused by coal mining, the permeability coefficient of fractured rock mass is higher several orders of magnitude than porous rock, Along with the influence of confined water or near the high pressure gas, and the seepage is non Darcy flow, prone to the seepage mutation. The origin of coal mine gas and water inrush accidents is mining fracture seepage in rock and mutation. Therefore, Study of non Darcy flow has important significance for the prevention and control of mine disaster, new technology can be developed based on the governance of coal mine of seepage disasters.

2 THE THEORY OF NON-DARCY SEEPAGE

Darcy's law was established by Darcy in 1856 (Darcy 1856), which is a standard approach in investigation of single phase fluid flow in microscopically both disordered and homogeneous porous media. The Darcy's law is often written as

$$-\nabla P = \frac{\mu}{K}\vec{V} \tag{1}$$

In Eq. (1), the permeability K is an intrinsic property of porous media. If the velocity becomes large enough, the Darcy's law is no longer sufficient. To describe the nonlinear flow in porous media, a quadratic term was introduced by Dupuit (Dupuit 1863) and Forchheimer (Forchheimer 1901) to generalize the flow equation, i.e.

$$-\nabla P = \frac{\mu}{K}\overline{V} + \beta\rho\overline{V}^2 \tag{2}$$

In Eq. (2), the factor β is generally called Forchheimer coefficient, is also called non-Darcy factor.

A most commonly used special form of Eq. (2) is Ergun equation (Sabrl Ergun 1952), which is a macro-scale model and is based on the hydraulic radius model

$$\frac{\Delta P}{L} = \frac{150\mu(1-\varepsilon)^2 v_s}{D_P^2\varepsilon^3} + 1.75\frac{1-\varepsilon}{\varepsilon^3}\frac{\rho v_s^2}{D_p} \tag{3}$$

Where P is the pressure, L is the length along the macroscopic pressure gradient in porous media, v_s is superficial velocity, μ is dynamic viscosity of fluid, ε is porosity of porous media, and D_p is average diameter of particles, ρ is density of fluid. The constants 150 and 1.75 in Eq. (3) were obtained from fitting 640 experimental data on spheres of different diameters. Compared Eq. (3) with Eq. (2), we get

$$K = \frac{D_P^2\varepsilon^3}{150(1-\varepsilon)^2} \tag{4}$$

$$\beta = 1.75\frac{1-\varepsilon}{D_p\varepsilon^3} \tag{5}$$

3 THE NONLINEAR DYNAMICS MODEL OF LAYERED ROCK MASS SEEPAGE

3.1 *The nonlinear dynamics model*

Set stope floor is composed of N layers of rock, i is rock number, see Figure 1, for the one-dimensional passive flow, while ignoring the volume and compressibility of water, the control equation for the rock dynamic system (Shu J S et al 2004, Schiavi C & Guglielmone F. 2012, Miao X Y et al 2007, Sun M G et al 2005)

$$\frac{\partial p}{\partial t} = -\frac{1}{\rho_0 \phi_0^{\,i} c_t^{\,i}} \frac{\partial w}{\partial x} \tag{6}$$

$$\frac{\partial w}{\partial t} = \frac{1}{c_\alpha^{\,i}} \left[-\frac{\partial p}{\partial x} - \frac{1}{\rho_0} \left[\frac{\mu}{k_i} w + b_i w^2 \right] \right] \tag{7}$$

When the system is in equilibrium, $\frac{\partial p}{\partial t} = 0$, $\frac{\partial w}{\partial t} = 0$, integral above second balance, and the sum of *i*, get

$$G_p = Aw + Bw^2 \tag{8}$$

In which

$$A = \sum_{i=1}^{n} \frac{h_i \mu}{\rho_0 h k_i} \tag{9}$$

$$B = \sum_{i=1}^{n} \frac{h_i b_i}{\rho_0 h_i} \tag{10}$$

$$G_P = \frac{p_0 - p_n}{\sum_{i=1}^{n} h_i} \tag{11}$$

The existence criteria of seepage system equilibrium state for the above layered rock mass is

$$D = A^2 - 4BG_p \tag{12}$$

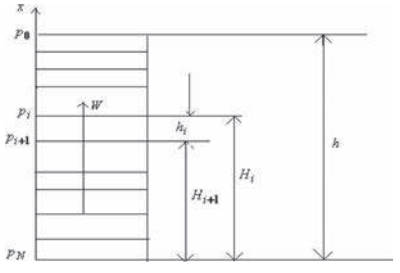

Figure 1. Dynamic model of rock seepage.

When D < 0, There is no equilibrium state, the system is not stable, we get specific instability conditions

$$g = \frac{4 \sum_{i=1}^{n} \frac{h_i b_i}{\rho_0 h_i} \frac{p_0 - p_n}{\sum_{i=1}^{n} h_i}}{\left(\sum_{i=1}^{n} \frac{h_i \mu}{\rho_0 h k_i} \right)^2} \tag{13}$$

From equation (4), (5), (13), we know, when $g < 1$, the occurrence of water inrush accidents is not caused by seepage instability.

Now we calculate the bottom floor is a single rock, the conditions of water not inrush, i.e. i = 1

$$g = 4 \frac{\Delta p b}{L \mu^2} \rho_0 k^2 = 4(bk\,\mathrm{Re} + (bk\,\mathrm{Re})^2) < 1 \tag{14}$$

Substituted the equations 4 and 5 into equation 14, we get

$$bk\,\mathrm{Re} = \frac{1.75 D_p\,\mathrm{Re}}{150(1-\phi)} \tag{15}$$

From equation 14, we get $-1.207 < bk\,\mathrm{Re} < 0.207$, From Eq. 15, we know that $bk\,\mathrm{Re} > 0$, Therefore, when $bk\,\mathrm{Re} <$ **0.207** satisfied, water inrush is not caused by seepage instability. i. e.

$$\frac{1.75 D_p\,\mathrm{Re}}{150(1-\phi)} < 0.207 \tag{16}$$

Change equation 16 to equality

$$D_p\,\mathrm{Re} = \frac{150 * 0.207(1-\phi)}{1.75} \tag{17}$$

The particle average diameter are respectively equal to 20 mm, 15 mm, 10 mm, 5 mm, get the relation of Reynolds number and porosity, see Figure 2.

From Figure 2 we can see that, when the Reynolds number in the corresponding figure below, floor water inrush will not caused by seepage instability, When the Reynolds number in the corresponding figure above, Floor water inrush will be caused by seepage instability. Figure 2 also shows that, the smaller of porosity and particle diameter, the larger of Reynolds number for causing loss of stability of seepage, i.e. the steady state is not easy to lose; otherwise, the larger porosity and particle diameter, the smaller of Reynolds number for causing loss of stability of seepage, the steady state is easy to lose.

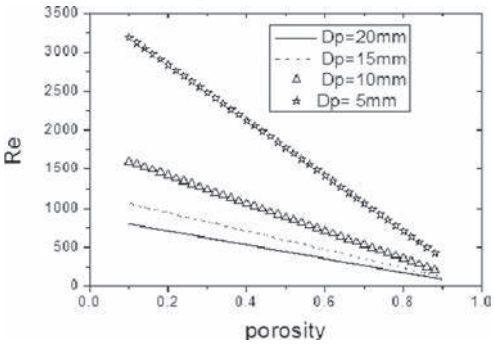

Figure 2. Relationship between Reynolds number and porosity.

4 CONCLUSION

Mining rock mechanics is a new subject for mechanics and mining engineering cross growth point, study on percolation theory is an important research direction. The seepage of mining rock mass which is fragmentation as the basic medium characteristic, has high nonlinear dynamic and random. Test method for new development, and on the basis of research, using random method and nonlinear dynamic systems is feasible. This paper mentioned some developments of this theory, further research is need to Continue.

The study on the principle of the compound perforating technology to improve rate of gas extraction

Jing-De Xu & Xin Yang
North China Institute of Science and Technology, Beijng, China

ABSTRACT: For the issues that low permeability coal seam gas extraction does not have obvious effect and low gas extraction rate, we propose the perforating technology which has been applied maturely in oil and gas exploration to increase coal seam porosity and improve gas extraction effect. Through analysing the feasibility of perforating technology applied in gas extraction and improving gas extraction rate, we can provide the evidence for the next step to carry out field testing and theoretical analysis roundly.

1 THE PRACTICAL BACKGROUND OF PERFORATING TECHNOLOGY

Due to coal and geological conditions, most of the high gas and outburst mines are difficult to extract in China, the fundamental reason is that coal seam permeability is poor. For low permeability and high gas coal seam, adopting conventional method to extract coal seam gas has the problems of long gas extraction cycle and low gas drainage efficiency. The main factor which determines whether coal seam permeability is good or bad is porosity of coal seam; therefore, the key measure to increase the coal seam porosity is to improve the gas extraction effect. (Lin 2006, Lin 1996, Hu 2002, Wan 2003 & Fushun 1984)

Over the years, the studies on gas extraction technology in China and abroad focuses on the goal of improving the coal seam permeability. The basic principle is using specific technology to change the original structure of coal, increase the porosity of coal seam with the help of outside force. The adopted technologies include Hydraulic Cutting Seam, Hydraulic Fracturing, Loose Blasting, Densely Borehole, Cross Borehole, Deep Hole Presplitting blasting and ect. (Zhou Zhou 1990 & Cheng 2009). Among these technologies, Hydraulic Fracturing and Deep Hole Presplitting blasting technology are more widely used.

Hydraulic Fracturing technology can use slotting to relieve coal seam pressure, cause deformation and damage of coal seam through underground stress, and increase the number of fractures in coal seam, so as to increase coal seam permeability (Sun 2010). However, the technology requires specialized fracturing equipment, relatively large quality and volume of conventional hydraulic fracturing equipment, it is inconvenience to transport, needs to prepare space for equipment and operating personnel to active. In the process of water injection, it needs to control the water injection pressure and fracturing time, the preparatory process is complex and the fracturing time is longer.

The Deep Hole Presplitting blasting technology is to use blasting stress wave as energy of destroying coal, the stress wave produces stress wave and superimpose each other in the process of stress wave propagating to the depths; it further accelerates the destruction of the coal, thus increasing the permeability. However, the technology needs to calculate and control parameters such as the blast hole depth, charge length in the hole, hole sealing, easy to produce misfire and thus leaves hidden danger.

In order to improve extraction rate and ensure safety, the new technology and new process must be developed. This paper mainly discusses the feasibility of compound perforating technology applied to the coal mine gas extraction.

2 THE PRINCIPLE OF COMPOUND PERFORATING TECHNOLOGY TO IMPROVE COAL SEAM PERMEABILITY

2.1 *The introduction of principle of perforating technology*

The perforating technology has became the main technical means to explorate the oil and gas field in China and abroad, at present the perforation completion has been widely used to mine oil and gas in the world (Joseph R.H. et al.). In China the perforation completion operation has been used in the oil and gas since 1950s and after development of 50 years, we have achieved remarkable achievements not only on the perforating technology but also on

the performance and supporting of perforating equipment. The main principle of the perforating technology is to use cavity effect to make the energy of explosive explode work on the shaped charge liner; then producing metal jet of high temperature, high pressure and high speed, penetrating the casing pipe and object and forming channel of certain depth (Wang 2002, Yuan 2002 & Wang 2006). The cavity effect refers to the product of explosive explode flying outward along the normal direction of explosive surface under high temperature, high pressure and high speed. Therefore, after exploding the explosive on the groove, there will appear a puff of agminated, high speed and high pressure explosive product stream; this makes the released chemical energy from explosive explode get together in a certain range. This is shown in Figure 1.

The compound perforating (Simon L. et al. 2004 & Jim G. et al. 1999) technology is a collection technology of perforation and high-energy gas fracturing, at the same time of perforating, the gas fracturing is conducting to the stratum, forming multiple cracks, increasing coal seam permeability and improving the ability of flow conductivity of coal gas.

2.2 *The mechanism of compound perforating technology crack coal*

During operation, the detonating cord ignites the propellant while detonating the perforating charge. First of all, the perforating charge penetrates the gun body and coal and forms a gallery between drilling and coal. Then the solid propellant explodes the second time, and instantly follows the high temperature airflow. Under the effect of dilate and extrude of high pressure gas, it washes out and fractures the perforating channel, forms crack of radial direction and axial direction and expand to multi-directions. Moreover, it forms multi-direction net crack in the coal channel and expand the perforating depth, increases coal seam porosity, improves coal seam permeability; and thus improves the effect of gas extraction.

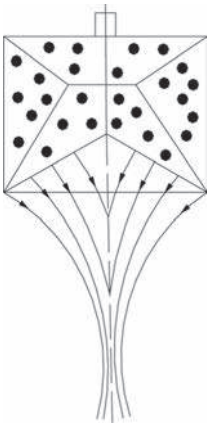

Figure 1. The principle of the perforating technology.

The feasibility of the compound perforating technology applied to improve the permeability of low permeable coal seam is mainly manifested in the following several aspects:

1. The oil and gas generally occurred in around the non-permeability rock, it reserves in adsorption state in the coal rock crack, this point is similar with the gas occurrence condition.
2. The explosive used in the perforating technology belongs to civilian explosive materials, it is conventional initiating explosive device and widely used in coal mine, and the management of explosive belongs to the normal management.
3. It is more safety than the deep hole presplitting blasting. After perforating, the residual metallic object in the object (coal seam) cannot produce or carry any oxidant (or oxygen in the air); therefore, the possibility of coal seam gas explosion is very small.
4. The perforating technology is maturely used in the oil and gas industry, it has easy popularization and application, simple technique, low cost and is easily to be operated and promoted.

3 THE EQUIPMENT AND PROCESS OF PERFORATING TECHNOLOGY

3.1 *The perforating equipment*

The perforating equipment includes perforating charge, perforator, gun body and the core part is perforating charge.

1. Perforating charge
   The perforating charge is made based on the principle of cavity effect; different shape explosive has different energy transfer ways. This is shown in Figure 2.
2. Perforator
   The perforator is cascaded of dozens of perforating charge to hundreds of perforating charge; this is the tool that uses the detonator and detonating cord to detonate the perforation. It can be divided into perforator with gun body and perforator without gun body. The perforator with gun body refers to the perforating charge equipped in the sealed steel tube; the perforator without gun body refers to single sealed perforating charge connected by seal wire, metal rod or thin metal belt, it perforates directly in the well.

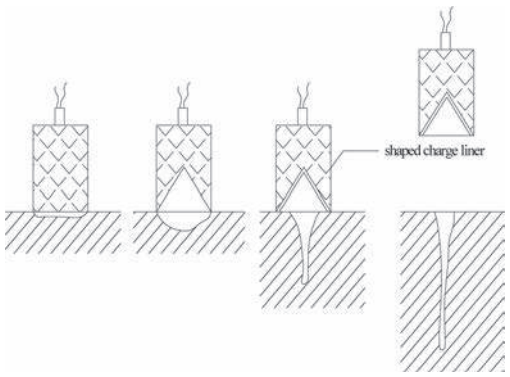

Figure 2. Different shape explosive has different destructive effect.

3. Gun body
   The gun body is an important part of a perforator, the main function as a carrier is to confine and absorb the energy produced by the perforating charge (the perforator without gun body do not have gun body).

3.2 *The perforating process*

According to process, the perforating can be divided into overbalanced perforating, underbalanced perforating, super-overbalanced perforating.

According to conveyed way, the perforating can be divided into cable conveyed perforation and tubing conveyed perforation (Wee H.L. 2002).

The cable conveyed perforation uses the cable (divided into perforator with gun body and perforator without gun body) to convey the perforator to underground by casing pipe or oil tube. It uses the perforating depth control technology to locate to align the target zone. Then the instrument on the ground supplies power to the perforation priming device and detonate the perforator; this can perforate the casing pipe, cement sheath, target zone and establish gallery between shaft and target zone.

The tubing conveyed perforation refers to concatenating all the perforators, which are used for perforating the oil and gas layer, into the end of the tube. This will form a hard-wired sting to run down to the well. By measuring the magnetic positioning curve or radioactivity curve, modifying the alignment of the depth allows perforator to correctly align with the perforation layers. Through using percussive type and pressurized type, these two types of detonating perforator perform a perforation to the destinated layers. During the perforating operations of highly deviated wells, horizontal wells, heavy oil wells, high pressure gas wells, sand wells and low permeability formations, each of them has their own unique advantages.

4 APPLICATION OF COMPOUND PERFORATING TECHNOLOGY TO IMPROVE THE RATE OF GAS EXTRACTION TECHNOLOGY ROADMAP

During the process of implementing the perforating technology into the oil and gas wells, the operations personnel are constructing on the ground. The issues related to construction process safety hazard is small, as a result, the probability of injury is very small as well. Meanwhile, coal mine production environment determines that workers and perforation preparation works have to be under the same operating environment during perforating process. Since there is a security risk, ensuring the safety of mine workers is the primary issue. The general technical routes are:

1. Measure the elastic modulus of coal and rock, the permeability and other basic parameters; the use of specialized software; the simulation for perforating fracture distribution formed by perforating in the operating environment. This information will all serve as reference for the trial.
2. According to the numerical simulation results, people select the appropriate perforating equipments, determine the drilling parameters (drilling diameter, length, spacing, angle, etc.) and sealing lengths.
3. After complete drilling, confirm the length of ignition wire according to the depth of drilling, then connect the ignition wire to the detonator wring in the perforating gun.
4. Using a dedicated thruster (such as stemmer) to drill the determined perforating charge into the hole bottom. Based on the actual needs, the perforating charge can be concentrated to perform a perforating operation.
5. When using hole sealing device for sealing, the sealing material has to be polyurethane, and the sealing length must not be less than 10 m, the ignition wire should be protected well when sealing, short circuit or open circuit is forbid to appear.
6. Performing a perforating operation after connecting the ignition wire to the initiation instrument well and electrifying in the safety area, the working process of perforating gun is shown in Figure 3.
7. After the operation is done and the job-site safety is confirmed, one must measure and record the data for the gas flow and density inside the hole. Such data will be compared with

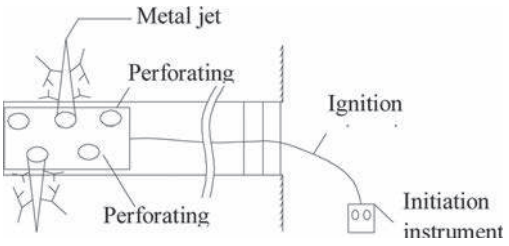

Figure 3. The process of perforating gun installation and perforating.

the gas parameters before implementing the perforating operation, and conclusions should be drawn.

Method of detecting in coal mine disaster warning internet of things based on SVM intruders optimized by Genetic Algorithm

Chang-Li Wang, Li-Min Sun, Sheng-Chen Yu, Jiang-Lan Huang, Xiao-Ju Wang & Hui Guo
Key Laboratory of Mine Disaster Prevention and Control Technology in Hebei Province, Yanjiao, Beijing-East, China
North China University of Science and Technology, Yanjiao, Beijing-East, China

ABSTRACT: In order to improve the detection correct rate of intruders in coal mine disaster warning internet of things, Support Vector Machine (SVM) classifier and Genetic Algorithm (GA) are applied synthetically to detect intruders in coal mine disaster warning internet of things in this paper. SVMs, as a new pattern classification technique, have been well recognized as a powerful computational tool for nonlinear problems. However, the standard SVMs are inefficient to achieve expected performance due to limitations in single kernel function. To enhance the SVMs' learning process and achieve expected performance, a hybrid kernel function has been proposed, which is composed of RBF kernel and polynomial kernel. GA is used to optimize the parameters of hybrid kernel to control misclassification. Experiments based on real-world data indicate that hybrid kernel SVM optimized by GA is higher in recognition accuracy than the general SVM and the detection right rate of intruders was above 91% for the KDD CUP 1999 data.

Keywords: Intruders, Support Vector Machine (SVM), Genetic Algorithm (GA)

1 INTRODUCTION

Software trespass can take the form of a virus, worm, Trojan horse, One of the two most publicized threats to security is the intruder (the other is viruses), generally referred to as a hacker or cracker. An intrusion is a formal term describing the act of compromising a system. And detecting either failed or successful attempts to compromise the system is called intrusion detection. In a nutshell, intrusion detection systems or IDS do exactly as the name suggests: they detect possible intrusions. The goal of IDS tools is to detect computer attacks or illegal access, and to alert the concerned people about the detection or security breach. An IDS installed on a network can be viewed as a burglar alarm system installed in a house. Though their methods are different, when an intruder/attacker/burglar is present, both can detect them, and both subsequently can issue some type of warning signal or alert (Rao, 2003).

Intrusion detection techniques can be partitioned into two main approaches: misuse detection and anomaly detection. Misuse detection methods attempt to model attacks on a system as specific patterns, and then systematically scan the system for occurrences of these patterns. Anomaly detection methods attempt to establish each user's normal activity profile, and to flag deviations from the established profile as possible intrusion attempts.

The intrusion detection problem is pattern classification problem in essence. Over the past decade, a lot of techniques, which involve the Bayesian parameter estimation (YU, 2008), data mining, artificial neural network techniques and support vector machine, etc have been applied to the field of intrusion detection.

As a good classifier, Support Vector Machines (SVM) certainly can perform better than some other methods, because it has higher generalization capabilities and is able to maximize the generalization performance of a trained classifier. In SVM, each kernel function has its own characteristic. Smits has pointed out that polynomial kernel function is a global kernel with weak learning ability and strong generalization ability, while RBF kernel is a local kernel function with just opposite characteristics. The 'good' characteristics of two or more kernel functions should be combined in order to enhance the whole performance of the SVM.

Thus, we make a combination of polynomial kernel and RBF kernel as the kernel of SVM. Genetic Algorithm (GA) is used to optimize the parameters of the hybrid kernel. In the application results, standard SVMs have been compared with SVMs with single kernel optimized by GA in the paper.

The rest of the paper is as follows. The necessary background knowledge is described in section 2. The dataset and the model of algorithm used in this paper are described in section 3. Experiment results are reported in section 4. Section 5 is conclusions.

2 PRINCIPLES OF HYBIRD-KERNEL SVM

A Support Vector Machine (SVM) is a class of supervised machine learning techniques. It is based on the principle of structural risk minimization. The ideal of SVM is to search for an optimal hyperplane to separate the data with maximal margin. Let *d*-dimensional input x belong to two classwhich was labeled

$$y_i\left(x_i, y_i\right), i=1,\ldots,n, x \in R^4, y \in \{+1,-1\}$$

his can be achieved by:

$$y_i[(w \cdot x_i)+b]-1+\xi_i \geq 0, \quad i=1,2,\ldots,n \tag{1}$$

If the data are not linearly separable, one can introduce slack variables ξ_i and instead minimize a modification of the above.

$$\min \phi(w)=\frac{1}{2}(w \cdot w)+C\sum_{i=1}^{n}\xi_i \tag{2}$$

Where C is a constant chosen a-priori.

In order to solve this problem, one can introduce Lagrange multipliers and consider the dual problem, under the constraints,

$$\sum_{i,j=1}^{n} a_i y_i=0, \ a_i \geq 0, \ i=1,2,\ldots,n \tag{3}$$

The optimal problem now is,

$$Q(a)=\sum_{i,j=1}^{n} a_i-\frac{1}{2}\sum_{i,j=1}^{n} a_i a_j y_i y_l (x_i \cdot x_j) \tag{4}$$

This is a two optimal problem, the only answer exists. According to Kuhn-Tucker condition, this optimal problem must satisfy,

$$a_i(y_i(w \cdot x_i+b)-1)=0 \tag{5}$$

Hence only the points x_i which satisfy, change equation will have non-zero Lagrange multipliers. These points are termed Support Vectors (SV). All the SVs will lie on the margin and hence the number of SVs can be very small. Consequently the hyperplane is determined by a small subset of the training set. Hence the solution to the optimal classified problem is given by,

$$f(x)=\operatorname{sgn}\left(\sum_{i=1}^{n} a_i^* y_i (x_i x)+b^*\right) \tag{6}$$

As the training of SVM is equivalent to solving a linearly constrained convex quadratic programming problem, the solution of SVM is always global optimal and absent from local minima. Actually, the solution is determined by only support vectors, which are a subset of training data points, so it can be represented sparsely.

Hybird kernel can be expressed in: $K=\sum \lambda_i K_i$, where K_i form a family of various kernel functions. The hybird coefficients λ_i are either simply required to be nonnegative or determined in the such way that the hybird kernel is positive semi-definite. So the hybird kernel function can be described as following ormula:

$$K=\lambda_1 K_{poly}+\lambda_2 K_{RBF}$$
$$S.T.\begin{cases}\lambda_1+\lambda_2=1\\ \lambda_1,\lambda_2 \geq 0\end{cases} \tag{7}$$

3 GENETIC ALGORITHM (GA)

GA is an artificial intelligence procedure based on the theory of natural selection and evolution (Chen, 2007). It is inspired by and named after biological processes of inheritance, mutation, natural selection, and the genetic crossover that occurs when parents mate to produce offspring. GA differs from conventional non-linear optimization techniques in that it searches by maintaining a population of solution from which better solutions are created rather than making incremental changes to a single solution to the problem.

Two important issues in GA are the genetic coding used to define the problem and the evaluation function, called the fitness function. Each individual solution in GA is represented with a string called the chromosome. The initial solution population could be generated randomly, which evolves into the next generation by genetic operators, such as selection, crossover and mutation. The solutions coded by strings are evaluated by the fitness function.

4 INTRUSION DETECTION MODELS BASED ON HYBIRD KERNEL SVM OPTIMIZED BY GA

4.1 *Hybrid kernel function*

Common kernel functions are divided two categories, global kernel functions and local kernel function. Global kernel function can display a perfect level of generalization performance, but its learning ability is poor. When global kernel function is used, the data points which are far between them can also affect the value of kernel function. On the other hand, local kernel functions have good learning ability, but their generalization performance

is poor and the dataset affect the value of kernel function only in small domain.

4.2 *GA-optimized procedure*

In intrusion detection, there are two types of misclassification errors. The type I of error occurs when non-intrusion are classified into intrusion group. The type II of error occurs when intrusion are classified into normal group. So the fitness function can be set as follows:

$$f = M(1 - TDR - FDR) \tag{8}$$

GA has been used to optimize RBF kernel width parameter σ^2 and punitive coefficients C_1, C_2 when $p = 1$ and $p = 2$ (p is the power of polynomial kernel) respectively. Here C_1, C_2 are the loss costs of and type II of errors. Chromosome length is 3; genetic algorism adopts real-valued encodings. The initial population is set to be 30. The True Detection Rate (TDR) measures the percentage of data correctly classified in the test set. The False Detection Rate (FDR) measures the percentage of data falsely classified in the test set that are detected falsely. M is an amplifying coefficient which ensures the change of fitness function is observable. We use proportional algorithm operator and arithmetic crossover algorithm, non-uniform mutation, mutation rate is set to be 0.07, $\lambda \in [0, 1]$, step length is 0.05 and the evolving generation is 2000. Some experimental results are reported in the following sections.

The GA-optimized procedure is as follows:

1. Initial Population
2. GA operation
3. Fitness Function Calculation
4. Maximum generation, If satisfies, then go to the step (5); If does not satisfy, go to the step (2).
5. Get optimized hybrid kernel SVM parameter

We have given a new intrusion detection model as follows:

1. Network Dataset;
2. GA parameter optimized by GA;
3. Classification by Hybrid kernel SVMs with optimized parameter;
4. Recognize possible intruders.

5 EXPERIMENTS AND RESULTS ANALYSIS

5.1 *Data set used in the experiments*

The dataset used is the KDD CUP 1999 data, which consists of approximately 4,900,000 data instances. Each instance is a 42-dimensional vector (label included). Each of the dimensions corresponds to an extracted feature value from a connection record obtained from the raw network data. The extracted features included the basic features of an individual TCP/IP connection, such as its duration, protocol type, number of bytes transferred, etc. Some of the attributes are nominal-valued. some of them are continuous-valued, and some are discrete-valued. Attacks fall into four main categories:

DoS: denial-of-service, e.g. SYN flood;
R2 L: unauthorized access from a remote machine, e.g. guessing password;
U2R: unauthorized access to local superuser (root) privileges, e.g. various "buffer overflow" attacks; Probing: surveillance and other probing, e.g. port scanning.

Each instance is a 42-dimensional vector (label included). There are eight discrete attributes, thirty-three continuous attributes and one label attribute.

5.2 *Experiments results*

To evaluate our method, we randomly chose 8,000 unique samples from the 10% sample of KDD Cup 1999 for our experiment, 5,000 samples are used to train the model and 3,000 to test. Since the KDD Cup 1999 is concerned with multi-classification. So we construct separately four classifiers to train dataset.

We compare the result based on our method with the result based on standard SVMs and SVMs with single kernel optimized by GA. The experiment results of four classifiers are shown in Table 1.

Based on those results, we can see the intrusion detection system based on ours method do not increase the training time of support vector

Table 1. Performance comparison of three methods.

Datasets	Algorithm	Accuracy (%)	False rate (%)
Probe	SVM	80.4	5.39
	SVM+GA	84.3	1.43
	Ours method	91.6	0. 61
DoS	SVM	81.3	5.58
	SVM+GA	85.7	1.52
	Ours method	90.5	0.37
U2R	SVM	81.8	5.07
	SVM+GA	84.6	0.89
	Ours method	90.7	0.50
R2L	SVM	82.7	4.73
	SVM+GA	87.3	0.79
	Ours method	92.3	0.52

machines classifier and can give higher recognition accuracy than the general SVM.

6 CONCLUSIONS

When Hybrid kernel SVM improved by GA is used as IDS, the overall performance of IDS can improved. Experiment results shown that this method was useful and the detection right rate of intruders was above 95% for the KDD CUP 1999 data. The study is motivated by the need to effectively control misclassification error and enhance the learning and generation performance of SVMs. We turn to hybird-kernel SVM composed of Polynomial kernel and RBF kernel which have been proved to be of compensatory characteristics. In order to control misclassification error, we use GA to optimize the parameters of hybird kernel function. All of above represent the feasibility and advantage of our method. But there are many respects which need the further study inevitably.

Future work is to improve the algorithm itself, we will reduce the degree of sensitivity of algorithm to noise, so as to improve the detection rate and lower rate of false positives further

School of Safety Engineering, North China Institute of Science and Technology, Beijing, China

ABSTRACT: The seam water injection is one of the coal dust prevention measures. However, due to the hydrophobic coal, the wetting effect of clean water is not ideal. By adding manner of the single surfactant and the two surfactants mixed in the water, the surface tension of the solution and the contact angle of 3 groups of coal samples were measured in this article. The experimental results show that two formulations, P_1: Fatty alcohol amide with Alkyl quaternary ammonium salt ratio of 2:1; P_2: JFC with Triton X-100 at a ratio of 1:1.

1 INTRODUCTION

Pre-wet coal is the most fundamental and the most effective means to reduce the dust which is caused by mining, loading and shipment of the coal. However, due to the poor wettability of the coal, only the water injection speed is low, and water capacity can not reach the dustproof requirements. When the surface active agent is added into the water, it can reduce the surface tension and wetting angle of the aqueous solution, thereby enhancing the ability of the solution wetting coal along the coal body fractured surface. Usually, according to its structure, surface active agent can be divided into cationic, anionic, non-ionic and mixed, which can reduce the surface tension of water, and change the characteristics of its contact angle. But for the cationic surface active agent, the cation is strongly adsorbed on the surface of the coal, which makes the coal surface leaving dehydrated state so that the absorbent capacity of the coal reduces, not achieve wetting coal acts. So, cationic surfactants are not suitable for coal seam water injection.

2 EXPERIMENTAL METHOD

2.1 *Coal sample preparation*

Particle size of 200 mesh accounted for more than 80% of the pulverized coal used in the experiment, and compressed into a diameter of 13 mm, a thickness of 2–3 mm coal cake. The coal cake was soaked in a saturated saline 24th, for the contact angle measurements.

2.2 *Measurement of surface tension and contact angle*

Bulleted lists may be included and should look like this:

- This experiment uses the FTA200 table interface analyzer to measure the contact angle and surface tension between the liquid and solid. Surface analyzer survey liquid and solid, shows the interfacial tension. The standard deviation of the contact angle measurement is smaller than 1°. The standard deviation of surface tension measurement is smaller than 0.5 m $N \cdot m^{-1}$.

3 SURFACTANT FORMULATION RESEARCH

Surfactant formulation starts from monomeric surfactants, then carry out the compound after choose preferably, control the type and proportion of the surfactant complex to alter the nature of the mixed solution. At last, elect a final surfactant formulation preferably which is based on surface tension and contact angle data.

3.1 *Study of the single surfactant*

According to the measurement of the wetting time of the prepared solution, the test surfactant is finally selected to the JFC, fatty alcohol amides, alkyl quaternary ammonium salt and Triton X-100 solution, which is in the ratio of the content of active agent and $CaCl_2$ is 1:9. Prepare of the salt solution of a concentration of 0.8% of the active

agent firstly, gradually dilute to 0.1%, 0.05% and 0.025% concentrations of the active agent solution. The experimental results are shown in Table 1.

As can be seen from Table 1, the JFC solution of high concentration (0.1%) of smaller surface tension, and the contact angle is small. But in the JFC solution of the medium (0.05%) and low (0.025%) concentration, the surface tension and contact angle are not big; fatty alcoholsamide, and Triton X-100 is low changes in solution surface tension of the medium and high concentrations, each concentration of fatty alcohol amides corresponding to the contact angle is small; In the Alkyl quaternary ammonium salt solution with low, medium and high concentration, the surface tension is larger, only high contact Angle is small, other concentration contact Angle is bigger. So, for single surfactant, the test is needed to find the compound formula to reduce contact Angle.

3.2 *Study of the complex surfactant*

When two kinds of surfactant are Compounded, choosing surfactant concentration was 0.05%, and the proportion of the two kinds of surfactant was 1:1. Preliminarily select two suitable compound formula, then do the concentration distribution in detail. The experimental results are shown in Table 2 and Table 3.

According to Table 1, the surface tension and contact angle of Fatty alcohol amide and Alkyl quaternary ammonium salts complex solution and JFC and Triton X-100 complex solution are less, it is necessary further study these detailed formula.

Derived from Table 2.2: the surface tension of 1:1 fatty acid amide and alkyl quaternary ammonium compound solution is minimum, corresponding to three sets of coal samples' contact angles which are small too. The surface tension and contact angle of JFC with Triton X-100 1:1 mixed solution are small. Both aboved solution can be studied in detail. Other complex formulations' surface tension and contact angle are big, which are not suitable for complex tests.

According to Table 3, 1) amide of fatty alcohols and alkyl quaternary ammonium salt ratio of 2:1, surface tension when compared with 1:1 is slightly higher, but the effect of the contact Angle of three kinds of coal sample decreased, better effect than 4:1 and for the most appropriate ratio formula is amide of fatty alcohols and alkyl quaternary ammonium salt ratio of 2:1. 2) For JFC and Triton X-100 in addition to the 1:1 ratio, the surface tension of the solution are rising with other proportion. The contact Angle of different coal sample has the tendency of increase, with the rest of the proportion is not suitable for carrying out the test. 3) The compound formula was finally determined:

Table 1. The surface tension and contact angle of salt solution.

Solution	Concentration (%)	Surface tension (dy/cm)	Contact angle (°)		
			1#	2#	3#
JFC	0.1	23.4	8.0	12.1	12.9
	0.05	26.3	20.8	34.4	31.7
	0.025	32.5	30.9	44.0	31.9
Fatty alcohol amide	0.1	23.7	9.3	13.5	12.1
	0.05	23.1	7.2	17.0	21.2
	0.025	25.8	15.2	20.5	26.4
Alkyl quaternary ammonium salts	0.1	28.5	7.6	11.4	14.5
	0.05	32.2	21.3	32.3	29.5
	0.025	38.8	36.0	43.0	46.3
Triton X-100	0.1	26.2	15.5	7.9	12.5
	0.05	26.5	21.7	40.8	37.4
	0.025	26.9	27.8	45.1	39.0

Table 2. 1:1 ration of surfactant solution of surface tension and contact angle.

Solution	Concentration (%)	Surface tension (dy/cm)	Contact angle (°)		
			1#	2#	3#
Fatty Alkyl	0.05 0.05	22.3	15.7	10.7	13.7
Fatty TritonX-100	0.05 0.05	24.9	9.2	8.2	24.6
JFC Alkyl	0.05 0.05	28.2	18.6	21.9	32.6
Alkyl TritonX-100	0.05 0.05	23.0	3.9	7.9	26.2
JFC TritonX-100	0.05 0.05	23.5	9.2	29.5	12.6
JFC Fatty	0.05 0.05	23.5	8.4	23.4	20.4

Table 3. The detailed formula surfactant solution of surface tension and contact angle.

Solution	Concentration (%)	Ratio	Surface tension (dy/cm)	Contact angle (°)		
				1#	2#	3#
Fatty alcohol amide Alkyl	0.05 0.05	1:1	22.3	15.7	10.8	13.7
		2:1	22.7	11.1	9.4	14.0
		4:1	22.8	22.3	13.5	8.3
JFC Triton X-100	0.05 0.05	1:1	23.5	9.2	29.5	12.6
		2:1	25.6	31.5	7.7	30.6
		4:1	24.6	29.4	9.5	13.0
		1:2	24.5	22.9	32.5	16.4
		1:4	26.7	15.8	26.1	30.0

based on the detailed proportion of surfactant with surface tension and contact Angle data contrast, getting the optimal formula.

4 CONCLUSIONS

Selected four kinds of surfactants on single surfactant measurement, it can be seen that the contact Angle is smaller in the relatively high concentrations of surfactant; In the low concentration of the contact Angle is bigger. Thus, it is necessary to do the two surfactant test. Comparison by the surface tension and contact angle, the optimal formula are P_1, P_2. P_1: The surface tension is 22.70 dy/cm, when the ratio of amide of fatty alcohols and alkyl quaternary ammonium salt is 2:1; P_2: The surface tension is 23.51 dy/cm, when the ratio of JFC and Triton X-100 are 1:1. For P_1, P_2, according to the choice of different coal condition such as the critical surface tension of the specific analysis.

Research on method of automatic recognition of coal mine water inrush sources based on Immune Algorithm and Back Propagation Neural Network

Sheng-Chen Yu, Li-Min Sun, Jiang-Lan Huang, Xiao-Ju Wang & Hui Guo
Key Laboratory of Mine Disaster Prevention and Control Technology in Hebei Province, Beijing-East, Yanjiao, China
North China University of Science and Technology, Beijing-East, Yanjiao, China

ABSTRACT: In order to improve the discrimination accuracy of underground water source, a method on recognition of flood water based on immune algorithm and Back Propagation Neural Network (BPNN) is developed in the paper by studying and analyzing the water chemical data. In this method, Immune Algorithm (IA) is used to preprocess the flood water data, extract key characteristics and reduce dimensions of experiment data set by characteristic analysis method, then BPNN is adopted to classify and recognize the flood water data. Experimental results show that the method is feasible and efficient, and the detection right rate of flood waters was above 93%.

Keywords: Water inrush source recognition, Mine water-bursting, Immune algorithm, Back Propagation Neural Network

1 INTRODUCTION

Over the years, the prevention and treatment of mine water disaster is always an important question for study or discussion of scientist, engineer and producer relevant to the research in the science field. In hydrogeochemical (referred to as the "water chemical") detection technology, the source of water (headwaters, waterhead) is analyzed and determined according to the ground water quality test results (CAO, 2010). More than eight indexes of water are tested generally on the ground. The method technology is an important means of mine water prevention and control work. In some complex area effect in recognition of mine water inrush, it is significant. It is a rapid, economic and practical method. At present, several following methods are commonly used. (1). mine water source is recognized by characteristic ion or ion ratio method; (2) Source of mine water in inrush (Chung, drench, collapse) is recognized synthetically by the water quality analysis and the isotopic analysis method; (3) Water source is determined by artificial tracer method; (4) Source of mine water in inrush is recognized by the establishment of mathematical distinguishing model. For example, through research, the people of a unit think that the content of NO_3^{-1} in Ordovician limestone water is 9~10.5 mg/L, the content of NO_3^{-1} in the water in other water-bearing stratum (aquifer) is very low. According to this result, with the help of the content of NO_3^{-1}, they determine whether Ordovician limestone water is projecting. However, the actual conditions are quite different with the results which are got in this manual and single index method, in some complex area. In addition, the computational efficiency of fuzzy clustering algorithm is very high, but its main shortcoming is that the model selected often does not reflect the probability structure of ground water quality index data, so the results obtained with these methods cannot reflect the real situation of data structure. In fact, mine water hazard source identification system is a complex project, not a simple classification problem. The many problems need to be studied further, for example, how to reduce the redundancy of the data to be analyzed, how to select the best characteristics, etc.

In this paper, a plurality of data of analysis of ground water quality test were pre-processed with Immune Algorithm (IA). The key characteristics of coal mine water inrush source data are extracted by characteristic analysis method. The complexity of the data is reduced by reducing the dimensionality of the data set. With the help of the data after dimension reduction, the Back Propagation Neural Network (BPNN) is trained. The coal mine water inrush source is recognized by the trained BPNN. Experiments show that if the source of mine disaster water is identified by the method developed in the paper, its accuracy can reach 93%. The more detailed introduction on the method is given below.

2 THEORY ON IDENTIFICATION OF MINE DISASTER WATER SOURCE

That mine water chemistry data are treated and the water sources are identified by mathematical model, is the inevitable result of the combination of modern geochemistry, mathematics and computer science. The process steps of recognizing water sources are as follows (Zheng, 2004):

1. According to the actual situation, first of all, the water chemistry model (or library of the water sample) of a mine, or an area (for example, Lu'an Group's mine), or water source in China's mine is established. The water sources in China's are mainly sandstone water, water in Ordovician limestone, the water in Tai limestone, the water in old lane and the cavity mined.

   In the mine that is mined below shallow sea, the mine water sources is mainly seawater; In the mine that is mined below reservoir or lake, the mine water source is mainly reservoir or lake water.
2. To obtain a plurality of indicators of water quality analysis in laboratory: for example, K^+, Ca^{2+}, Mg^{2+}, SO_4^{2-} (sulfate), PH, Fe (iron), NO_2^- (nitrite), I (iodine) and T (temperature).
3. To establish a mathematical modeling method for judging water inrush, such as application of artificial intelligence method to determine the source of water.
4. When the water is determined to be the Ordovician limestone, or water-accumulating old kiln and gob area water, which may bring about water disasters in coal mine, the preventive measures can be taken. When the water is determined to be the other water or water with small harm, the coal mine can be mined normally.

3 IMMUNE ALGORITHM (IA)

Immune algorithm is a new algorithm which is designed in recent years according to enlightenment of the biological immune system (Mo & Jin, 2002).

Antigen, namely, an alien cell, everything which is not physical things will be probably antigen, for example, pathogen, pollen, a transplanted organ. Antibody is able to swallow the antigen. The molecule of antibody is a kind of protein, for example, white blood cell.

According to the biological immune principle, with the help of the division and differentiation of cell, the biological immune system produces automatically corresponding antibody against the antigen which invades life body. This process is called immune response. In the immunity reply process, part of antibodies is preserved as memory cell. When the similar antigen invades the life body once more, the memory cell is activated and produces rapidly the massive immune bodies. This causes that 2nd reply is more intense than the primary reply, which manifests memory function of the immune system. A kind of immune body and another kind of immune body are also promoted and suppressed mutually, to maintain the multiplicity of the immune body and the balance of immunity. This kind of balance is carries on according to the density mechanism, namely the density of the immune body is higher, and the immune body is suppressed more. The density of antibody is lower, the antibody is promoted more. This manifests self-adjustment function of the immune system.

Immune Algorithm (IA) is essentially a new algorithm for searching for multimodal function and global optimization. It has the ability of massively parallel processing information, the ability of strong learning, the ability of memory, the ability of recognition, adaptability and robustness, the ability of self-organization and the ability of maintaining the diversity.

In the immunity algorithm, the antigen is corresponding to the objective function and variant kind of constraint conditions; and the immune body (antibody) corresponds with the optimal solution. The kissing degree between the antibody and antigen corresponds with the match degree of solution and the objective function.

That a set of characteristics for identification of mine water hazard source are selected by immune algorithm is proposed in this paper. This group of characteristics is few, and the classification ability is strong. With this group of characteristics, the accuracy rate of the recognition of mine water is high. In this paper, the quantitative weight represents the importance of characteristics.

In the immune algorithm, the problem is solved as antigen, the antigen corresponding to the objective function and constraints, antibody corresponds to the solution of the problem, namely the antibody corresponding to the optimal solution, between antibody and antigen affinity corresponds to matching and objective function.

1. Coding mode

   In the immune algorithm, the antibody and antigen encoding are binary code, code and character code. There are a few gray coding. Binary search capability, but also has the advantages of simple operation of the cross, variation. Therefore, this paper uses binary coding.

   For the P attribute of mine water hazard source data, namely P characteristics, each attribute is represented by the length of the E binary string. The decimal number correspond-

ing binary represent the weight value of the attribute. Each antibody contains P × E binary.

2. Initial antibody population
   Randomly generated in the solution space of the N candidate solution as the initial antibody, which is randomly selected characteristics group N, N is the number of antibody group.
3. Calculation methods of antibody concentration
   Antibody concentration is mainly used to maintain the diversity of antibodies, improve the local search ability. Antibody concentration calculation method is based on the Euclidean distance between antibodies and information entropy method based on two. This paper adopts the method based on information entropy. Information entropy (Information Entropy) used to indicate that the population diversity of antibodies, antibody concentration obtained by the method of antibody population average information entropy.

   A number of N antibody, gene number of antibodies for M, allele number is S. First define the symbol (~) probability in loci, i.e.:

$$p_{ij} = \frac{\text{The total number of i symbols appear in locus j}}{N}$$

   As the information entropy of the gene, defined as:

$$H_j(N) = -\sum_{i=1}^{N} p_{ij} \log_2 p_{ij} \tag{1}$$

   The average information entropy for the whole group:

$$H(N) = \frac{1}{M} \sum_{j=1}^{M} H_j(N).$$

   At this time, the antibody, affinity, i.e. similarity of antibodies and for: $ay_{vw} = \frac{1}{1+H(2)}$, Among them: $H(2)$ is the average information entropy antibody and antibody group, if $H(2) = 0$, and the same, then the antibody. The concentration of antibody: $C_v = \frac{1}{N} \sum_{W=1}^{N} aC_{VW}$, Among them: $aC_{vw} = \begin{cases} 1 & ay_{vw} \succ Tac1 \\ 0 & other \end{cases}$, for a given threshold.
4. Calculation method of affinity between antibody and antigen
   Antibody and antigen affinity for the antibody to the antigen that the degree of recognition, using the Back Propagation Neural Network (BPNN) to get false negative rate and false positive rate as a method to identify mine water, then calculate affinity.

   Against the group of antibodies by decoding operation, into various attributes of mine water source identification data (characteristics) of the weight value, the weight value of 6 characteristics larger as the input of BPNN, and then use BPNN to record data for training and recognition.

   Coal mine water inrush source data reference standard set, get the recognition of the false positive rate and false negative rate. The affinity between antibody and antigen is defined with the false positive rate and false negative rate. The formula for the definition:

$$ax_v = \frac{1}{a_1 \times e_v + a_2 \times m_v} \tag{2}$$

   Where a_1 and a_2 determined with the experience value.
5. The reproduction rate of computing antibody expectations
   On the basis of antibodies expected breed rate selection operation, concentration of the natural immune system regulation mechanism, namely the antibody concentration low promotion, suppression of antibody concentration is high, thus maintaining the diversity of antibodies, prevent the algorithm into premature convergence; antibody and antigen affinity of antibody development to better control of the individual direction.

   Antibody expectation reproduction rate:

$$e_v = \frac{ax_v}{c_v}$$

6. New antibody group
   Arrangement of the descending antibody group according to expectation reproduction rate, and taking the first antibody composition of parent population, antibody at the same time, before the specified number of deposited into the memory. Select, crossover, mutation operation of parent groups are new groups, and then remove the memory antibody from memory, together constitute a new generation of antibody population.
7. Termination Rules
   The running of immune algorithm is stopped with the number of iterations. After all the iterative operation is finished, the individual in memory is the optimal solution of immune algorithm.

4 BACK-PROPAGATION NEURAL NETWORK

The study results of modern neurophysiology and anatomy show that, the human brain is extremely complex, which is consisting of 101000 million neurons, which are intertwined, and constitute a reticular structure. The human brain can finish such as intelligence, thinking, emotion and other senior neural activity. It is considered to be an information processing system which is the most perfect, the most effective. Back Propagation Neural Network (BPNN) is an abstraction and simulation of some basic characteristic of the human brain by mathematical method. It is a nonlinear information processing system of imitating human brain structure and function. The essence of BPNN reflects a functional relationship between the input and output of the network. By selecting different model structures and the activation function, the different neural network can be formed, to obtain different relationship of input and output, and achieve different design purpose, complete different tasks. Neuron is the basic processing unit of neural network. Neuron is generally nonlinear element with multiple input and single output. The output of neuron is not only influenced by the input signal, but also affected by other factors within neurons, so in the modeling of artificial neurons, an additional input signal, known as the deviation (bias), sometimes called threshold, is often also added.

For example, for a neuron with n input component, the input components of the $x_j(j - 1,2,...n)$, the corresponding weight coefficients w_{j1}, w_{j2}, w_{j3},...,w_{jn}, namely the

connection weights, indicate synaptic connection strength between synaptic 1, 2, 3....., N and the j neuronal.

For the convenience of analysis, we divide the process into three mathematical calculation steps:

1. The weighted – each input signals are weighted in different degree weights coefficient;
2. Sum – sum of the combination effect of all of input signals are calculated;
3. Mapping – the output results are calculated by transfer function.

The biological neuron response process is described in the mathematical equations in follow.

Column vector represents the input vector:

$$X = [x_1 \cdots x_2 \cdots x_n]^T \tag{3}$$

Row vector $\boldsymbol{w}_j$ represents connection weights vector of the neural:

$$W_j = [w_{j1} \cdots w_{j2} \cdots w_{jn}] \tag{4}$$

Pure input s_j of the neurons j is:

$$S_j = \sum_{i=1}^{n} w_{j1} + \theta_j = W_j X + \theta_j \tag{5}$$

Where θ_j in the formula —— threshold.

After pure input of the neuron is alternated with transfer function, the input y_i of the neurons is:

$$y_i = f(S_j) = f\left(\sum_{i=1}^{n} w_{ji} x_i + \theta_j \right) \tag{6}$$

If the θ_j is processed in $x_0 = 1$ method, then the formula (4) expressed as:

$$y_i = f(S_j) = f\left(\sum_{i=1}^{n} w_{ji} x_i \right) = f\left(W_{ji} x_i \right) \tag{7}$$

Thus, with formula, we describe the process of obtaining the information of response to the signal received by a neuron.

For the various topologies of BPNN, its operation process can be divided into two stages: The first stage is learning (or training) of BPNN; the second stage is association of BPNN (namely, to recognize the source of water of water- inrush).

In the learning process of BPNN network, through inputting some sample patterns to the BPNN network, the weights of each layer of BPNN are adjusted constantly by following the learning rules, the algorithm, so that the input and output of BPNN approximate the given sample model to a certain precision.

The essence of BPNN learning is that BPNN recognizes the inherent law in the information through the input and output information. Learning methods can be divided into two kinds: one kind is supervised learning or learning with teacher; another is the unsupervised learning or teacherless learning. On the basis of weight adjustment way, learning can be divided into off-line learning and on-line learning.

Table1. Comparison of results of identification hazard water source by methods and method developed in the paper.

Different recognition methods	Identification of hazard water source correct rate
Method developed in the paper	93%
Manual single index method	43%
Cluster analysis method	71%
Method of fuzzy cluster analysis	75%
Discriminative analysis	70%

Table 2. The part of the data and results of identification hazard water source by method developed in the paper.

Recognition results	Actual water types	Temperature (T)	Chlorine (Cl^-)	Kalium (K^+)	Calcium (Ca^{2+})	(Mg^{2+})	(SO_4^{2-})	PH	Fe	NO_3^{-1}	I
Sandstone Water	Sandstone Water	35	106.0	16.51	571.44	164.320	495.0	7.328	0.310	237.45	1.220
Ordovician limestone water	Ordovician limestone water	45	184.0	57.83	783.05	367.190	1125.787	7.591	2.640	46.0	1.540

A learning process of BPNN consists of two sub-processes: the forward propagation of the input data and the reverse propagation of error. The weights and threshold of BPNN are adjusted by the gradient method, so that sum of square error of BPNN output is minimum. In the algorithm, firstly, the network weights and threshold are given small initial value, and then, with selecting a training sample set, the error relative to this sample set is computed. If the gradient of each layer can be known, according to the learning rule, the connection weights and thresholds are updated, until the algorithm convergence.

5 MODEL OF IDENTIFICATION OF MINE WATER HAZARD SOURCE BASED ON AI-BPNN

The mine water hazard source identification data are pretreated by Immune Algorithm (IA), to extract the main characteristics associated with the water source identification. The processed data are classified and recognized with the BPNN. The specific steps of recognition of the water source are as follows:

(1) to obtain a plurality of data set obtained by analysis and test of ground water quality; (2) The data set is pretreated by Immune Algorithm (IA); (3) BPNN is trained by the data set pretreated; (4) The mine water source is recognized by the trained BPNN; (5) The decision response to result of recognition.

6 RESULTS AND DISCUSSION

In this paper, with the water samples in mine and borehole in a gold mine of Hebei area and the coal mines of Lu'an Group, the water sources were recognized with a plurality of index data obtained by analysis and test of the ground water quality. The water sources of flooding to mine of the two mining area are mainly divided into 4 categories: water in Ordovician limestone water, sandstone, Tai limestone water, the old kiln water, ground water and fault oxidation zone water. The results of water resource recognized by the method developed in the paper in the two mine area are given in Table 1.

From Table 1 and Table 2, we can see that the right rate of water-bursting source identification obtained by several different methods is different. The right rate of water-bursting source identification obtained by the method developed in the paper is the highest, which proves that the method developed in the paper is effective and feasible.

Gas drainage technology of inner interlocked low tail laneway in extraordinarily high gas working face

Q. Ye, Z.Z. Jia, H.Z. Wang & Y. Pi
School of Energy and Safety Engineering, Hunan University of Science and Technology, Xiangtan, Hunan, China
Hunan Province Key Laboratory of Safety Mining and Technology of Coal Mine, Xiangtan, Hunan, China

ABSTRACT: The gas emission of 33207 working face is extraordinarily high, according to the characteristics of coal seam occurrence and gas emission in 33207 working face, the gas emission rate and the gas emission sources were measured and analyzed by the element method, and then the law of gas emission and gas migration were obtained. According to previous experience and gas control technologies, the gas drainage technology of the upper corner by the inner interlocked low tail laneway was adopted, based on the U type ventilation and the gas drainage from extracting seam. Finally, its drainage technique, application conditions and problems were acquired. By using these measures, the gas emission and gas over-limitation of 33207 working face was solved effectively, and the risk of coal and gas outburst was eliminated, thus ensuring safety production. The gas drainage technology of the upper corner by the inner interlocked low tail laneway can offer the instruction for similar working faces with extraordinarily high gas emission.

1 GENERAL SITUATION AND EXISTING PROBLEMS OF 33207 WORKING FACE

The III_2 coal seam is the upper adjacent seam of III_3 coal seam, which is an unworkable coal seam and has unstable occurrence, its average thickness is 0.6 m, and the average distance from III_3 coal seam is 25 m. The IV_1 coal seam is the lower adjacent seam of III_3 coal seam, which is also an unworkable coal seam and has unstable occurrence, its average thickness is 1 m, and the distance from III_3 coal seam is 12–15 m. The III_3 coal seam has three working faces: 33206 working face, 33207 working face and 33208 working face. The 33207 working face is the main working face, its length and crossheading length are 156 m and 1596 m, respectively; the left of 33207 working face is the 33206 working face which will be mined out soon, and the right of 33207 working face is the 33208 working face which is being prepared. The thickness of III_3 coal seam is 2.6–4.5 m, the average is 3.9 m; and the inclination angle of III_3 coal seam is 0°–15°, the average is 5°. The structure of III_3 coal seam is simple: the false roof consists mainly of carbon mudstone and carbon shale, with a thickness of 0.1–0.3 m; the immediate roof is mainly composed of siltstone and fine sandstone, with a thickness of 9.8 m; and the floor consists mainly of fine sandstone, with a thickness of 8.17 m. At the beginning of production, the coal mine has potential safety hazards; because the absolute gas emission rate is 115.8 m^3/min, the relative gas emission rate is 42.72 m^3/t, and moreover, the gas emission has an obvious increase tendency.

According to the gas emission from the mined working faces and 33207 working face, the main problems in 33207 working face were found as follows: (1) both the upper and lower adjacent seams of III_3 coal seam (i.e. the III_2 coal seam and the IV_1 coal seam) are unworkable, and they are fairly close to III_3 coal seam; thus the gas emission rate from the adjacent seams is so great that the gas concentration in 33207 working face is frequently in the critical state and the gas concentration in the upper corner of 33207 working face often exceed limitation; (2) the U+L ventilation mode was adopted in 33206 working face, the coal spontaneous duration is short, the coal spontaneous combustion is easily caused by the air leakage from the gob, which has negative influence on production; (3) the existing ventilation system and gas drainage measures cannot solve the gas overrun efficiently.

2 ANALYSIS ON GAS EMISSION LAW OF 33207 WORKING FACE

The gas emission in mined working faces, field measure results and theoretical analysis showed that the gas in 33207 working face is mainly from mining coal seams, adjacent seams (including wall rocks), and gobs, the gas from adjacent seam

enter the mining coal seam and the gob through wall rock fractures. The gas emission sources in 33207 working face were measured by the element method; the results showed that the air leakage rate from the gob is –27 m^3/min, the gas emission rate from the gob is 2.81 m^3/min, the gas emission rate from the coal wall and the fallen coal is 0.887 m^3/min. According to the measure data, the results can be obtained as follows: (1) the gas emission rate from the gob accounts for 76% of the total gas emission rate, the gas emission from the coal wall and the fallen coal accounts for 24%, more than 91% of the gob gas passes through the upper corner and enters the 33207 working face; (2) the air leakage quantity into the gob from the element where the upper and lower corners are and the air leakage quantity from the gob are obviously larger than that in other elements, which shows that the measures on stopping air leakage from the upper and lower corners can efficiently prevent and control gas emission from the gob; (3) the gas concentration is fairly large within the range of 30–50 m from the upper corner, and the gas concentration in the upper corner is obviously larger than other elements, which indicates that the gas emission zone is mainly around the upper corner; thus the key of gas prevention and control in 33207 working face focuses mainly on the gas control in the upper corner. To solve gas emission and gas over-limitation in 33207 working face, based on previous experience and gas control technologies (Lin & Cui 1998, Lin & Hu 2006, Lin & Zhang 1996, Ye et al. 2006, Yu 1992, Zhang et al. 2006, Zhou 1999), the U type ventilation and the gas drainage from extracting seam were used, and then the gas drainage technology of the upper corner by the inner interlocked low tail laneway was analyzed and practiced.

3 GAS DRAINAGE TECHNOLOGY OF UPPER CORNER BY INNER INTERLOCKED LOW TAIL LANEWAY

3.1 *Principle of inner interlocked low tail laneway*

The inner interlocked low tail laneway is located in the windward side of the upper corner in the fully mechanized caving face and in the top layer of the coal seam, meanwhile, drainage pumps are used for gas drainage, which ensures that the inner pressure of the inner interlocked low tail laneway is lower than the ventilation pressure of the return airway, making the air inlet constantly in a low pressure area. This has two functions (Hao 2006): on one hand, a greater air suction flow field exists in the air inlet of the inner interlocked low tail laneway, and a very obvious "air curtain wall" is formed, which drains high concentration gas in the upper corner and makes the gob gas move towards the inner interlocked low tail laneway; on the other hand, the inner interlocked low tail laneway communicates with the gob, and a ventilation channel is formed, which closures the gob gas between the inner interlocked low tail laneway and the intake airway, greatly reducing gas emission from the gob, so as to prevent and control gas in the upper corner of the gob.

3.2 *Characteristics of inner interlocked low tail laneway*

The characteristics of the inner interlocked low tail laneway can be described as follows:

1. Gas split-flow: the inner interlocked low tail laneway is an important channel of gob gas spit-flow, which changes the gas emission path, reduces the gas pressure in the upper corner, and thus guarantees production safety in the mining face; the larger the proportion of gas quantity drained by the inner interlocked low tail laneway is, the less the gas entering the return airway will be and the lower the gas concentration in the return airway will be.
2. Generating negative pressure point: the tail of the inner interlocked low tail laneway straightly enters the gob and generates the negative pressure point, which makes the gob gas move towards the inner interlocked low tail laneway and prevents the gob gas from moving towards the working face and the return airway (namely, closures the gob gas between the inner interlocked low tail laneway and the intake airway), thus reducing gas quantity into the upper corner and solving the problem on gas accumulation in the upper corner effectively. The motion of negative pressure point depends on the roof caving, generally speaking, the better the effect of roof caving is and the shorter the distance between the negative pressure point and supports is, the better the effect of gas drainage will be.

3.3 *Layout of inner interlocked low tail laneway*

The measure on gas concentration in the gob indicates that the gas concentration is increasing within a 30 m range from working face to the gob, which is the accumulation region of high concentration gas in the gob. Besides that the roof caving lags behind the coal cutting; thus, along the trend of working face, the air inlet of the inner interlocked low tail laneway must stretch into the coal wall of the gob above 8 m (namely, the air inlet of the inner interlocked low tail laneway must be behind the air return inlet of the mining field at working face more than 8 m), so as to collect the

gas emitted from the gob along the airflow direction. Along the vertical direction of working face, the air inlet of the inner interlocked low tail laneway is near 5 m vertically above the floor of the mining field at working face, so as to collect gas emitted from the coal (rock) of the gob roof after releasing pressure.

3.4 *Design of inner interlocked low tail laneway*

A great deal of gas emitted from the 33207 gob enters working face via the upper cutting-off line, thus generating gas over-limitation between the upper supports, at the top of the upper supports, at the tail beam, and in the upper corner. In order to solve this problem, according to the gas flow theory on pore medium of mining field, a gas drainage laneway at the roof is laid along the coal seam roof and parallel to the return airway, which is referred to as 33207 inner interlocked low tail laneway. The 33207 inner interlocked low tail laneway is laid at 5 m location below the return airway and parallel to the roof, its cross section area is 3.8 m × 2.4 m; and it will cave spontaneously with advancing working face (see Figs. 1–3). The mining of 33206 working face which is immediately adjacent to 33207 working face has influence on the coal within 33207 inner interlocked low tail laneway; for example, the pressure on coal seam is fairly large, the coal is instable, and part of coal seam is separated. During the mining at working face, the key of designing the inner interlocked low tail laneway is that the inner interlocked low tail laneway cannot cave before the top coal caving by fully-mechanized supports and can ensure the air return channel unobstructed. If the inner interlocked low tail laneway above the supports falls down, the gas at the end of supports is difficult to drain after the top coal caving; if the reserved inner interlocked low tail laneway before the working face falls down and communicates with the working face, the ventilation system of the working face is

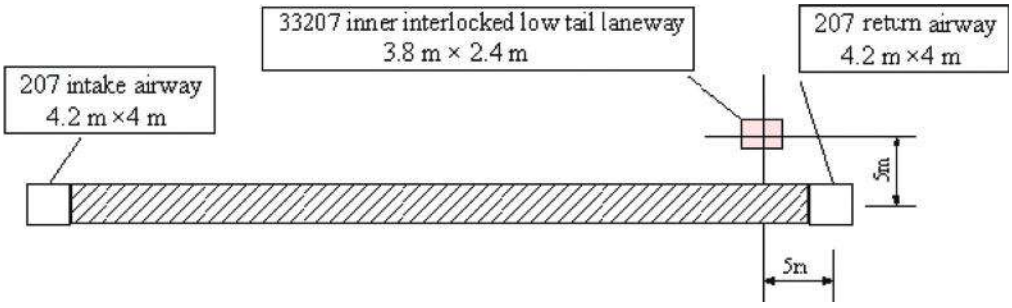

Figure 1. The structure diagram of 33207 inner interlocked low tail laneway.

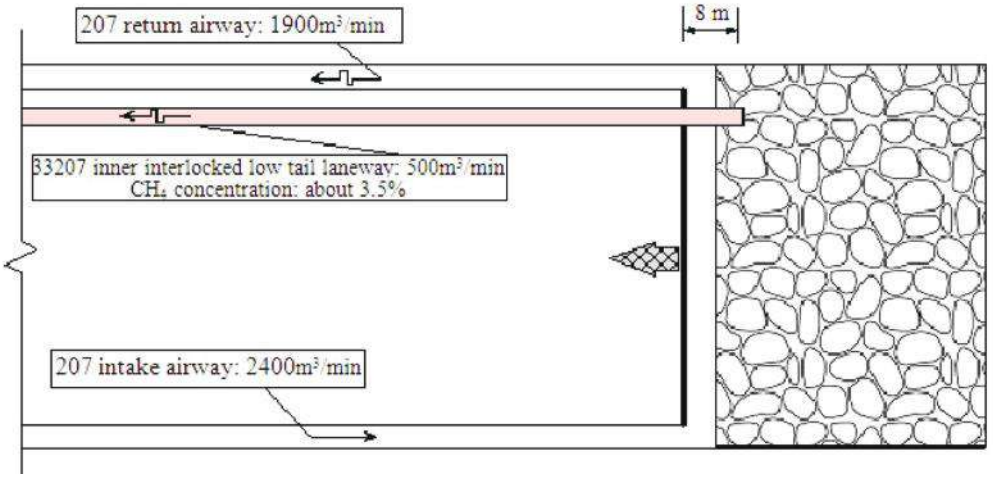

Figure 2. The plan of 33207 inner interlocked low tail laneway.

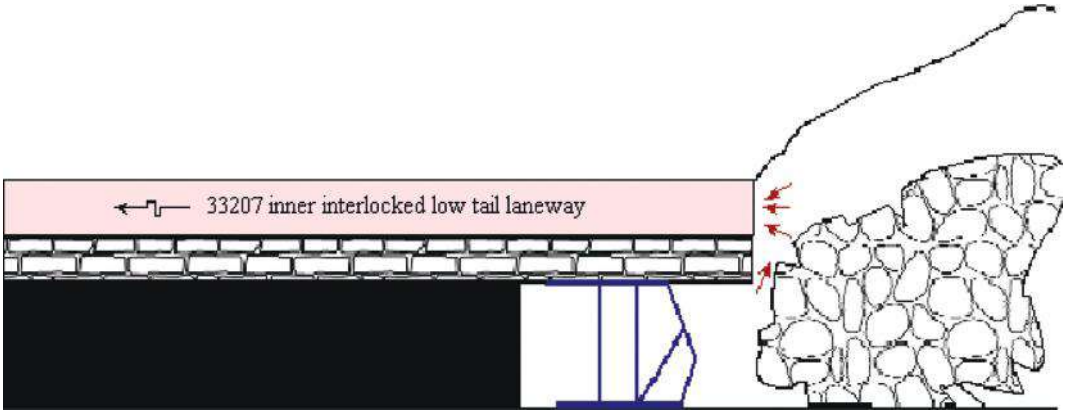

Figure 3. The side elevation of 33207 inner interlocked low tail laneway.

disordered and the coal cannot come out normally from the working face; therefore, the most important is that the coal pillars from the position above the supports to the inner interlocked low tail laneway and the coal pillars from the position before the working face to the inner interlocked low tail laneway cannot cave. In order to achieve the effect of the inner interlocked low tail laneway in mining process, the support on the roof and the wall of the inner interlocked low tail laneway should be strengthened, a rock layer with a thickness of at least 1.2 m should remain at the floor and the support top (as shown in Fig. 1 and Fig. 3). In the mining process at 33207 working face, in order to acquire the changes of roof and coal, the working face roof below the inner interlocked low tail laneway and a range of 10 m at the end of supports should be monitored in real time, thus providing a basis for further improvement in the layout of the inner interlocked low tail laneway.

4 PROBLEMS ON GAS DRAINAGE TECHNOLOGY OF UPPER CORNER BY INNER INTERLOCKED LOW TAIL LANEWAY IN PRACTICE

The theoretical analysis and field practice show that gas emission rate from the gob is large, the gas drainage in the gob is a vital part of gas control, and the inner interlocked low tail laneway can drain the gas in the upper corner effectively. Meanwhile, in practice, the following problems should be paid attention to:

1. The thickness of coal between the inner interlocked low tail laneway and the working face should be controlled strictly (Xue & Zhang 2007).

   In tunneling, according to the height design of the inner interlocked low tail laneway, the height design of the working face, and the coal seam thickness, the construction should be implemented in strict accordance with the design. The method for drilling holes into coal seam floor from the inner interlocked low tail laneway is used, and the thickness between the inner interlocked low tail laneway and the roof of the working face can meet the design; so that the caving of the inner interlocked low tail laneway caused by the insufficient thickness in the front or upper of supports is avoided, thus making the ventilation system work normally.
2. The negative pressure of the inner interlocked low tail laneway must be satisfied firstly (Wang 2004).

   The practice in the mining process at 33207 working face found that the relative pressure difference between 33207 inner interlocked low tail laneway and the return airway of 33207 working face must be satisfied firstly, which is the precondition to ensure that 33207 inner interlocked low tail laneway works effectively. The relative pressure difference between the mouth of 33207 inner interlocked low tail laneway and the return airway of 33207 working face is 450–550 Pa by adjusting the adjusting wall. Meanwhile, sufficient air quantity should be guaranteed in 33207 inner interlocked low tail laneway and cannot make gas emission from the gob increase.
3. The effect of coal caving at the supports of tail segment must be ensured (Wang 2004).

   According to the principle of the inner interlocked low tail laneway, the gas split-flow in the gob can achieves good results, only when the outlet of the inner interlocked low tail laneway in the gob is unobstructed. Based on the field observation, the gas emitted from the coal within the range of 10 m near the upper corner

can be drained mainly by the air quantity in the upper corner; therefore, in the process of mining, the coal caving is carried out reasonably according to the specific situation of the roof, which can be controlled effectively in the field, and also changes the negative pressure point of the inner interlocked low tail laneway in the gob. The practice has proved that on the premise that the gas problem in the upper corner is solved effectively, it is better that the negative pressure point moves forward; because when the negative pressure point moves backward, the influence on the gob is relatively large, directly showing that the windblown mine gas concentration is large, thereby increasing the gas emission quantity in the area, which is bad for gas control.

4. The air leakage at the roof of the inner interlocked low tail laneway and the roof of transportation roadway should be prevented (Wang 2004).

   If human factors or objective factors make the inner interlocked low tail laneway and the transportation roadway air leakage, then the system will become an U type ventilation system and the inner interlocked low tail laneway will not work. When the air leakage appears; corresponding measures should be adopted, for example, the air duct cloth is covered at the air leakage spot of supports' canopy or the adjusting wall is constructed at the mouth of the inner interlocked low tail laneway to adjust the air quantity of the inner interlocked low tail laneway, meanwhile, the air brattice is hung at the drive end unit to solve the gas accumulation in the upper corner.
5. The support management of the inner interlocked low tail laneway and the roof management below the inner interlocked low tail laneway should be strengthened (Xue & Zhang 2007).

In general, the inner interlocked low tail laneway is laid immediately adjacent to the return airway; in the process of the support design, the roof pressure between roadways and the dynamic pressure should be taken into account; especially in the mining process, the effect of the inner interlocked low tail laneway should be considered fully, that is to say, the support strength should be considered fully, otherwise, once the mining causes the collapse of the inner interlocked tail roadway, all the previous efforts will be wasted.

During the period of mining, the roof management below the inner interlocked tail roadway is also very important, pulling supports must be in time or in advance, supports must be tightened, and the face sprag must be reinforced. Besides that the mining height must be controlled strictly at coal-cutting, in order to prevent the working face and the inner interlocked low tail laneway cutting through; meanwhile, the support maintenance in this segment should be strengthened so as to avoid the negative influence of support faults on advancing.

5 EFFECT AND ASSESSMENT OF GAS CONTROL

Based on the U type ventilation and the gas drainage from extracting seam, which were adopted at working face, the gas drainage technology of the upper corner by the inner interlocked low tail laneway was analyzed and practiced. The gas in the gob and the upper corner of 33207 working face with extraordinarily high gas emission was controlled effectively by adopting this gas drainage technology, which improves the production capacity of the working face.

1. Based on the measure and analysis on gas emission, the migration law and gas emission sources at 33207 working face were obtained: the gas concentrations increased gradually from the inlet side to the return air side, the gas concentration from the air inlet to the middle of working face is not high, the gas concentration from the middle of working face to the upper corner is relatively high, especially, the gas concentration within a range of 30–50 m near the return air side is higher. The region near the upper corner is the high gas concentration area, and is also the main channel where the gob gas enters the working face; thus the emphasis of gas control at the working face is to avoid the gas over-limitation in the upper corner, which can be solved by the inner interlocked low tail laneway.
2. When the inner interlocked low tail laneway is adopted to drain gas in the upper corner; a greater air suction flow field exists in the air inlet of the inner interlocked low tail laneway, and a very obvious "air curtain wall" is formed, which drains high concentration gas in the upper corner and prevents the gas in the gob moving towards the working face and the return airway, thus achieving the purpose of gas control in the upper corner.
3. In practice, the following aspects should be paid attention to in the layout and management of the inner interlocked low tail laneway: firstly, the thickness of coal between the inner interlocked low tail laneway and the working face should be controlled strictly; secondly, the relative pressure difference between the inner

interlocked low tail laneway and the return airway should be ensured within a appropriate range, the sufficient air quantity should be guaranteed in the inner interlocked low tail laneway and cannot make gob gas emission increase; thirdly, the coal caving should be controlled, which can increase the permeability of the inner interlocked low tail laneway, and cannot make the inner interlocked low tail laneway lose the effect of gas drainage due to the short circuit of air flow; fourthly, the inner interlocked low tail laneway should be laid in the roof fracture zone, and the distance between the inner interlocked low tail laneway and the floor of the working face should be chosen according to the characteristics of coal occurrence, so as to avoid the phenomenon that the coal winning machine cuts through the inner interlocked low tail laneway; fifthly, the support management of the inner interlocked low tail laneway and the roof management below the inner interlocked low tail laneway should be strengthened.

Research on airflow catastrophic of side branches induced by gas pressure in upward ventilation

Aitao Zhou, Kai Wang, Zeqi Wu & Yifeng Jiang
School of Resource and Safety Engineering, State Key Laboratory of Coal Resources and Mine Safety, Beijing, China University of Mining Research on Airflow Catastrophic of Side Branches Induced by Gas Pressure in Upward Ventilation and Technology, Beijing, China

ABSTRACT: In order to analyze the law of airflow catastrophic of side branches induced by gas pressure in upward ventilation after dynamic of outburst disappearing, one dimensional unsteady-state flow momentum equation of gas flow is established. Combined with circuit airflow pressure balance equation, this equation is used in static and dynamic analysis on airflow catastrophic of side branches induced by gas pressure in upward ventilation. The research results show that gas pressure is produced in upward ventilated roadway when gas flowed by; when the gas pressure is great enough, the air flow in side branches reverses. Whether the air flow in side branches reverse is affected by their own length and initial velocity. In order to prevent the air flow reversal in the side branches, it is necessary keep the fan normal operating, and avoids adding resistance in external system. The research results may be of important theoretical and practical significance for outburst accident rescue as well as effective prevention of the occurrence of secondary accidents.

1 INTRODUCTION

Once coal and gas outburst occurs, shock wave and gas flow is produced transiently (Wang and Zhou et al, 2012; Wang and Zhou et al, 2011; Wang and Zhou et al, 2012; Wang and Zhou et al, 2012; Wang and Zhou et al, 2011; Zhang and Wang et al, 2010; B. Basil Beamish and Pete J. Crosdale, 1998), which induces mine airflow catastrophic in two ways: (1) The overpressureof outburstshock wave (C.Y. Chen, 2010; Wang and Zhou et al, 2012), when the resistance is lower than the outburst overpressure in one roadway, the airflow will reverse in the roadway. (2) The gas pressure (Y. Zhou and X.S. Wang, 2000; Fluegge G, 1969). After the dynamic of outburst disappears, gas pressure induces airflow catastrophic further. Upward ventilation system is widely used in working face. But few studies have been done on the law of airflow catastrophic of side branches induced by gas pressure in upward ventilation (W. Dziurzynski and J. Krawczyk, 2008; F. Otuonye and J. Sheng, 1994; W. Y. Cheng and G.X. CHEN, 2000; Zhang and Sun et al, 2007; A. Britan and G. Ben-Dor et al, 2006; Cheng and Liu et al, 2004). This paper established one dimensional unsteady-state flow momentum equation of gas flow after dynamic of outburst disappears, which, combined with circuit pressure balance pressure equation, is used in static and dynamic analysis on airflow catastrophic of side branches induced by gas pressure in upward ventilation. The research results are of important theoretical and practical significance for outburst accident rescue as well as effective prevention of the occurrence of secondary accidents.

2 MECHANISM OF AIRFLOW CATASTROPHIC INDUCED BY GAS PRESSURE

Gas pressure is practically the increment of natural pressure when outburst occurs. Because density of the gas containing high-concentration methane is lower than that of the air, after outburst occurs, the differential of density leads to pressure difference. This gas pressure can be defined as, where C is gas concentration (%), ρ_a is air density (kg/m^3), ρ_m is density of gas with methane (kg/m^3), Z is height differential of roadway (m). Characteristic of gas pressure are as follows:

1. Gas pressure is proportional to height differences of the roadway. The greater the height differences are, the greater gas pressure is. In entries, height difference is small, as well as the gas pressure; gas pressure is not obvious in entries. But when flow of high-concentration methane flows though inclined drifts or vertical shafts, gas pressure is quite obvious.

2. The higher the methane concentration of air flow is, the greater the gas pressure is. When methane concentration in roadways falls to zero, gas pressure is not existence.
3. When gas pressure produced in upward ventilated roadways, its direction is the same as fan pressure, which is positive for the fan; when gas pressure produced in downward ventilation roadways, its direction is opposite to fan pressure, which is negative for the fan.

3 ESTABLISHMENT OF ONE DIMENSIONAL UNSTEADY-STATE FLOW MOMENTUM EQUATION

This equation considers gas flow in roadways as one dimensional fluid flow, properties of gas flow are uniform in the same section of roadways. Considering flow of micro-unit along roadway branch *i* as object of study, the one dimensional unsteady-state flow mometum equation is as follows:

$$\rho \frac{du}{dt} = -\frac{\partial P}{\partial s} + \rho F - j - j_D \delta(s - s_D) + h_f \delta(s - s_f) \quad (1)$$

Where:

$\frac{du}{dt}$ is acceleration of airflow micro-unit (m/s^2), $\frac{\partial P}{\partial s}$ is press acts in *s* direction per unit volume (N/m^3), ρF is body force on per unit volume, $F = -g\frac{dz}{ds}$ is average density of airflow micro-unit (kg/m^3), g is acceleration of gravity (m/s^2), z is elevation ofroadway i (m), j is resistance of per unit longth (Pa/m), j_D is pressure drop by regulator at s_D(Pa), h_f is pressure of fan at *si*(Pa), $\delta(s–s_D)$, $\delta(s–s_f)$ is dirac δ function, when $s \neq s_D$, $\delta(s–s_D) = 0$; when $s \neq s_f$, $\delta(s–s_f) = 0$; when $\varepsilon > 0$, $\int_{s_D-\varepsilon}^{s_D+\varepsilon} \delta(s - s_D)ds = 1$, $\int_{s_f-\varepsilon}^{s_f+\varepsilon} \delta(s - s_f)ds = 1$; The last two terms show that pressure drop by regulator and pressure of fan are variables related to position, and that they located at corresponding positions s_D and s_f. In this equation, s is space coordinate along axial direction of roadways (m), s_D is coordinate of points where there is a loss (m). s_f is coordinate of fan's position (m).

Integrating along roadway *i* from $s = 0$ to $s = Li$. Because on-way resistance is: $\int_0^{L_i} jds = R_i|Q_i|Q_i$, and $R_i$is windage of roadway *i*, $R_i = \frac{\lambda\rho_i}{8}\frac{L_i U_i}{A_i^3}$, Ns^2/m^8; A_i is section area of roadway, m^2; $Q_i = u_i A_i$, is volume flow rate, m^3/s. pressure drop of road *i* $H_i = -\int_0^{L_i} dP_i$, equation (1) can be translated into:

$$\rho_i L_i \frac{du_i}{dt} = H_i - g\int_0^{L_i} \rho dz - R_i|q_i|q_i - j_{D,i} + h_{f,i} \quad (2)$$

Let $K_i = \frac{\rho_i L_i}{A_i}$, $u_i = u$ is air flow velocity of roadway *i*, m/s, $\rho_i = \frac{1}{L_i}\int_0^{L_i} \rho ds$ is average density of the air flow in roadway *i,* one dimensional unsteady-state flow momentum equation is established:

$$H_i = K_i \frac{dQ_i}{dt} + g\int_0^{L_i} \rho_i dz + R_i|Q_i|Q_i + j_{Di} - h_{fi} \quad (3)$$

4 THEORETCAL ANALYSIS AIRFLOW REVERSAL OF SIDE BRANCHES INDUCED BY GAS PRESSURE IN UPWARD VENTILATION

When outburst occurs in mine, airflow catastrophic will occur in intake airways connected with the source of outburst because of the great impact force produced by gas flow transiently released and of the gas pressure after the dynamic of outburst disappears, of which the most typical is airflow reversal of side branches. Therefore, this paper will use one dimensional unsteady-state flow momentum equation established above to analyze law of airflow reversalof side branches induced by gas pressure when upward ventilation airflow catastrophic occuring.

4.1 *Static analysis of airflow reversal of side branches induced by gas pressure in upward ventilation*

Fig 1 is schematic diagram of Gas flow in upper ventilation (Y Zhou, 2006).

Side branch b is considered as object of investigation, and by branch b, the ventilation network can be divided into two parts: the left part and the right part; Branch a is the roadway with a large amount of gas influx because of outburst, C branch can be divided into BF and FA, where FA is atmospheric branch; h_i represents gas pressure in branch a; and h_v fan pressure in the left; R_i synthesized windage of branch a; R_0 synthesized windage of left part; Q_0 represents air quantity of the left part, Q_i the right; R_b and Q_b represents windage and air quantity of side branch b respectively.

On condition that the original wind direction from A to B remains the same, establishing airflow pressure balance pressure equation along circuit

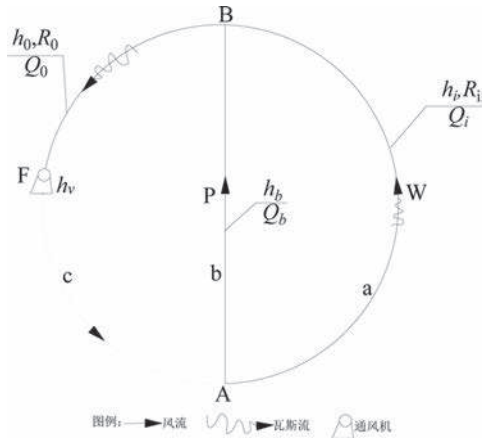

Figure 1. Gas flow in upper ventilation.

FAPB:

$$h_v = R_0 Q_0^2 + R_b Q_b^2 \tag{4}$$

Also, establishing airflow pressure equation along circuit FAWB:

$$h_v + h_i = R_0 Q_0^2 + R_i Q_i^2 \tag{5}$$

The two formulas subtracting and devition:

$$\frac{h_i}{h_v} = \frac{R_i Q_i^2 - R_b Q_b^2}{R_0 Q_0^2 + R_b Q_b^2} < \frac{R_i Q_i^2}{R_o Q_o^2} \tag{6}$$

When airflow direction in branch b remain the same and $Q_b > 0$, $Q_b > Q_i$.

So it can be deduced that:

$$\frac{h_i}{h_v} < \frac{R_i}{R_0} \tag{7}$$

According to inequality (7), the following conclusion can be drawn:

1. After outburst occurs, if cannot be controlled timely, great gas pressure will be produced in upward ventilated airways methane flowing by. When hi is great enough, airflow in side branch b will reverse.
2. In order to prevent airflow reversing in side branches, a h_v big enough is need to guarantee. Therefore, it is necessery to keep the fan normal operating, avoid adding resistance in external system, and keep R_0 as low as possible.
3. Taking measures in outburst branch a to increase resistance to increase internal windage R_i, which can reduce air supply to outburst branch, then reduce gas pressure, and have the effect of stability of the side branch airflow.
4. Airflow direction in side branches has nothing to de with its own windage.

4.2 *Dynamic analysis of airflow reversal of side branches induced by gas pressure in upward ventilation*

Practically, in the process of outburst, the quantity of gas released is changing. Correspongdingly, flow in the network is consequentially a dynamic process. It can be said that dynamics is the basic feature of the state of flow after outburst. Therefore, it is very necessary to consider the dynamic feature of airflow when analyzing airflow catastrophic induced by gas pressure.

Circuits airflow pressure balance equation is still tenable to dynamic network flow. Press differences between the first note and the last note can be obtained one dimensional unsteady-state flow momentum equation. For easy analysis, assuming that branch a, branch b and branch c has the same section area.

First of all, considering the condition that airflow remain the same direction in any branch, and define that: velocity of airflow is positive when airflow direction remain the same as it is before outburst, when the opposite is negative. Solve the press differences between two ends of branch a, b and c in Fig. 1 respectively, based on the one dimensional unsteady-state flow momentum equation.

1. Branch b

$$H_{APB} = -\int_{APB} \frac{\partial p}{\partial x} dx \tag{8}$$

Where:

H_{APB} is press difference between note A and B in branch b(Pa).

By substitution of the formula (3) and the equivalent diameter $d = \frac{4A}{U}$ into formula (8), and regardless of other additional power and resistance loss, the conclusion is drawn as followed:

$$H_{APB} = -\int_{APB} \left(\rho \left(\frac{\partial u}{\partial t} + \rho g \sin a + \frac{\lambda \rho u^2}{2d} \right) \right) dx \tag{9}$$

Where: a is inclination of branch b.

Because there is no gas flow in branch b, density of airflow in this branch can be consider as constant, viz:

$$\rho_b = \rho_0 = const \tag{10}$$

Where:

ρ_b is density of airflow in branch b (kg/m^3), ρ_0 is density of airflow in the network before outburst (kg/m^3).

Institute formula (10) into formula (9), the result is:

$$\begin{aligned} H_{APB} &= \rho_0 \left(\frac{\partial u}{\partial t} + \frac{\lambda u^2}{2d} \right)_b L_b + \rho_0 g \sin a L_b \\ &= \rho_0 \left(\frac{\partial u}{\partial t} + \frac{\lambda u^2}{2d} \right)_b L_b + \rho_0 g (z_B - z_A) \end{aligned} \tag{11}$$

Where:

L_b is length of branch b(m), Z_A is height of note A(m), is height of note B(m).

2. Branch c

FA is atmospheric branch, so wind pressure in this branch is 0, and:

$$H_{BFA} = H_{BF} - h_v = -\int_{BF} \frac{\partial p}{\partial x} dx - h_v \tag{12}$$

Where: H_{BFA} is pressure differences between the first note B and the last note A in branch c(Pa), H_{BF} is pressure differences between two ends of BF in branch c(Pa), h_v is pressure of fan (Pa).

By institution of formula (3) and the equivalent diameter $d = \frac{4A}{U}$ into formula (12), it is obtained that:

$$\begin{aligned} H_{BFA} = &\int_{BF} \left[\rho \frac{\partial u}{\partial t} + (\rho - \rho_0) g \sin a \right] dx \\ &+ \int_{BF} \frac{\lambda \rho u^2}{2d} dx + \rho_0 g (z_A - z_B) - h_v \end{aligned} \tag{13}$$

Let, $h_{BFA} = -\left\{ \int_{BF} \left[\rho \frac{\partial u}{\partial t} + (\rho - \rho_0) g \sin a \right] dx \right\}$, formula (5.15) becames:

$$H_{BFA} = \underbrace{-h_{BFA}}_{(1)} + \underbrace{\int_{BF} \frac{\lambda \rho u^2}{2d} dx}_{(2)} + \underbrace{\rho_0 g (z_A - z_B)}_{(3)} - \underbrace{h_v}_{(4)}$$

Where, the 2nd term is the whole frictional resistance of branch c, and the 3rd term is position pressure differences between two ends of branch c when airflow is steady state; the 4th term h_v is the power of fan, and the first h_{BFA} is gas pressure in static analysis. Obviously, h_{BFA} contains more than gas pressure in static analysis. h_{BFA} not only contains the partial gas pressure caused by density differential, but also contains extra power produced by flow with variable velocity of airflow (resistance).

3. Branch a

$$H_{AWB} = -\int_{AWB} \frac{\partial p}{\partial x} dx \tag{14}$$

Where:

H_{AWB} is pressure differences between the first note A and the last note B of branch a(Pa).

By institution of formula (3) and the equivalent diameter $d = \frac{4A}{U}$ into formula (14), it is obtained that:

$$\begin{aligned} H_{AWB} = &\int_{AWB} \left[\theta \rho \frac{\partial u}{\partial t} + (\rho - \rho_0) g \sin a \right] dx \\ &+ \int_{AWB} \frac{\lambda \rho u^2}{2d} dx + \rho_0 g (z_B - z_A) \end{aligned} \tag{15}$$

Let, $h_{AWB} = -\int_{AWB} \left[\rho \frac{\partial u}{\partial t} + (\rho - \rho_0) g \sin a \right] dx$ and formula (15) becomes:

$$H_{AWB} = \underbrace{-h_{AWB}}_{(1)} + \underbrace{\int_{AWB} \frac{\lambda \rho u^2}{2d} dx}_{(2)} + \underbrace{\rho_0 g (z_A - z_B)}_{(3)}$$

Any term has the similar meaning with branch c.

Based on circuit wind pressure balance equation, it is obtained in the circuit constructed with branch a and b that:

$$H_{AWB} - H_{APB} = 0 \tag{16}$$

By institution of formula (15) and (11) into formula (16), it is obtained after simplification that:

$$h_{AWB} + \rho_0 \left(\frac{\partial u}{\partial t} \right)_b L_b = \int_{AWB} \frac{\lambda \rho u^2}{2d} dx - \rho_0 \left(\frac{\lambda u^2}{2d} \right)_b L_b \tag{17}$$

Again based on circuit wind pressure balance equation, it is obtained in the circuit constructed by branch b and c that:

$$H_{BFA} + H_{APB} = 0 \tag{18}$$

By institution of formula (13) and (11) into formula (18), it is obtained after simplification that:

$$h_{BFA} + h_v - \rho_0 \left(\frac{\partial u}{\partial t} \right)_b L_b = \int_{BF} \frac{\lambda \rho u^2}{2d} dx + \rho_0 \left(\frac{\lambda u^2}{2d} \right)_b L_b \tag{19}$$

Let formula (17)/(19):

$$\frac{h_{AWB}+\rho_0\left(\frac{\partial u}{\partial t}\right)_b L_b}{h_{BFA}+h_v-\rho_0\left(\frac{\partial u}{\partial t}\right)_b L_b}=\frac{\int_{AWB}\frac{\lambda\rho u^2}{2d}dx-\rho_0\left(\frac{\lambda u^2}{2d}\right)_b L_b}{\int_{BF}\frac{\lambda\rho u^2}{2d}dx+\rho_0\left(\frac{\lambda u^2}{2d}\right)_b L_b}<\frac{\int_{AWB}\frac{\lambda\rho u^2}{2d}dx}{\int_{BF}\frac{\lambda\rho u^2}{2d}dx}$$

viz:

$$\frac{h_{AWB}+\rho_0(\frac{\partial u}{\partial t})_b L_b}{h_{BFA}+h_v-\rho_0(\frac{\partial u}{\partial t})_b L_b}<\frac{\int_{AWB}\frac{\lambda\rho u^2}{2d}dx}{\int_{BF}\frac{\lambda\rho u^2}{2d}dx} \quad (20)$$

Inequality (20) is deduced out under the condition that the airflow direction in branch b remains the same. It can be proved that inequality (20) will not be tenable when airflow in branch b stagnating or beginning to reverse. So inequality (20) is the conditional inequality guaranteeing airflow in branch b remains the same.

Practically, the process of airflow reversal in side branch b is a process that its wind quality becomes smaller and smaller, and tends to 0, which becomes negative at last. In the process that airflow tends to reverse but before it reverses, the velocity of airflow in branch b is always becoming smaller, that is inequality $\frac{\partial u}{\partial t}|_b<0$ is always tenable. So inequality (20) can be modified into:

$$\frac{h_{AWB}-\rho_0\left|\frac{\partial u}{\partial t}\right|_b L_b}{h_{BFA}+h_v+\rho_0\left|\frac{\partial u}{\partial t}\right|_b L_b}<\frac{\int_{AWB}\frac{\lambda\rho u^2}{2d}dx}{\int_{BF}\frac{\lambda\rho u^2}{2d}dx} \quad (21)$$

Let: $x_1=\left|\frac{\partial u}{\partial t}\right|_b L_b$, $x_2=h_{AWB}$, $x_3=h_v+h_{BFA}$, the left side of inequality (21) can be expressed as:

$$\frac{h_{AWB}-\rho_0\left|\frac{\partial u}{\partial t}\right|_b L_b}{h_{BFA}+h_v+\rho_0\left|\frac{\partial u}{\partial t}\right|_b L_b}=\frac{x_2-\rho_0 x_1}{x_3+\rho_0 x_1} \quad (22)$$

Let $H(x_1,x_2,x_3)=\frac{x_2-\rho_0 x_1}{x_3+\rho_0 x_1}$, it is obtained that:

$$\frac{\partial H}{\partial x_1}=-\frac{\rho_0(x_2+x_3)}{(x_3+\rho_0 x_1)^2} \quad (23)$$

Based on the circuit wind pressure balance equation in the circuit constructed with branch a and c, it is obtained that:

$$h_{AWB}+h_v+h_{BFA}=\int_{AWB}\frac{\lambda\rho u^2}{2d}dx+\int_{BF}\frac{\lambda\rho u^2}{2d}dx \quad (24)$$

The right side of Equation (24) is always more than 0, and the left is equivalent with x_2+x_3, so $x_2+x_3>0$; and therefore, $\frac{\partial H}{\partial x_1}=-\frac{\rho_0(x_2+x_3)}{(x_3+\rho_0 x_1)^2}<0$.

Formula (23) shows that, $H(x_1,x_2,x_3)$ is decreasing function of the left of inequality (21) about $\left|\frac{\partial u}{\partial t}\right|_b L_b$. That is the bigger $\left|\frac{\partial u}{\partial t}\right|_b L_b$ is, the easier formula (23) will tenable, and the less possible airflow reversal occurs in branch b. Therefore, the greater the air flow velocity in branch b is before it contains methane, inevitably, the greater the rate velocity changing with time $\left|\frac{\partial u}{\partial t}\right|_b$ if it deduces to 0 in the same time. Therefore, it can be concluded qualitatively that: when upward ventilated branches filled with methane, it is difficult for airflow reversing in side branches that has great length and original velocity. That is, when outburst occurs, airflow reversal of side branches in upward ventilation is related with the length and original velocity of the branch.

4.3 *Comparison of static and dynamic analysis*

After outburst, when methane exits in upward ventilated branches, by the static method, whether airflow reversal will occur in side branches has no relation to its own windage. While in dynamic analysis, airflow reversal of side branches in upward ventilation is related with the length and original velocity of its own. According to the calculation formula, the length of roadways is a important factor that affects their windage. Consequently, there are some contradictions between the conclusions of static and dynamic analysis. The reason is that the contradictions are caused by the ignorance of dynamic changes in static analysis of the flow in network after outburst. Steady flow is assumed in static analysis, which is to say $\frac{\partial u}{\partial t}=0$. But in practical process, the flow is unsteady, even dramatic changing, in the network. Therefore, the steady assumption of static analysis is deviated from the fact obviously in a outburst in networks. And because of $\frac{\partial u}{\partial t}=0$, there will naturally not appear $\left|\frac{\partial u}{\partial t}\right|_b L_b$ in the conclusion of static analysis. For side

branch b, $\rho_0 \left|\frac{\partial u}{\partial t}\right|_b L_b$ in inequality (21) is actually hysteresis effect of flow inertia on airflow changing. The fundamental limitation of static analysis is not considering dynamics of flow, thus ignoring the inertia effect of airflow. According to the analysis of the dynamic method, although it cannot be said that airflow reversal of side branches must be related to its own windage (because length is just one of the factors that influence windage, windage can be the same with different length), at least it can be believed that the conclusion of static analysis that airflow reversal of side branches has nothing to do with windage is somewhat limited. Except this, other conclusions of static analysis have no contradiction with that of dynamic analysis, which can, therefore, still be considered reasonable.

5 CONCLUSIONS

1. After outburst occurs, great gas pressure will be produced in upward ventilated airways methane flowing by. When gas pressure is great enough, airflow in side branches will reverse.
2. In order to prevent the air flow reversal in the side branches, it is necessary to keep the fan normal operating, and avoid adding resistance in external system.
3. When outburst occurs, airflow reversal of side branches in upward ventilation is related with the length and original velocity of the branch.
4. The conclusion of static analysis that airflow reversal of side branches has nothing to do with windage is somewhat limited.

Experimental study of horizontal strata deep rock roadway crack propagation and strength criteria

M.C. He, Y.Y. Peng, F. Zhao, Y.B. Wang, Y. Zhang, Y.Q. Sun & W.L. Gong
State Key Laboratory for Geomechanics and Deep Underground Engineering, Beijing, China
School of Mechanics and Civil Engineering, China University of Mining and Technology, Beijing, China

ABSTRACT: In order to obtain deep mine of layered rock mass surrounding rock stability, we carried out physical modeling to study the deformation and failure processes of roadways subjecting to a plane loading scheme. The variation of inner strain of the model in the whole process were recorded by strain gauges and camera separately. Then the crack initiation and propagation during failure process of the tunnel were analyzed by combining the stress filed in the physical model and the experimental photos. As a conclusion, under geostress caused by gravity and tectonic factors, crack initiation occurs at the bottom of the tunnel at first. Then the cracks appear on the side and top of the tunnel. Ultimately, general failure of the tunnel is credited to crack propagation, coalescence with the increasing loads.

1 INTRODUCTION

With the increment of 100–250 m every ten years for the excavation depth in mine in eastern China, it can be noted that many coalmine will enter into 1000–1500 m depth (He 2004). Due to the complex environment where the deep rock mass stay (high stress, high temperature, high karsts water pressure and intense exploitation disturbance), deep rock behave great difference in mechanical properties comparing to that in shallow mining (He & Qian 2010). And most of the coal-bearing strata with layered structures are located in the tunnel of the hard roof and floor where the dynamic disasters such as rockburst and coal and gas outburst often met. Thus, investigation of deep mining stability of coal stratum is of important significance.

Many researchers have done a great amount of research on the stability of roadway surrounding rock. For example, the effect of stress field direction on roadway surrounding rock stability has been studied (Huang et al. 2012). Numerical simulation is applied to study the case of Jin Chuan deep tunnel (Yi 2012). And the numerical analysis methods of rock mass and principle of geo-mechanical model test have been clearly pointed out (Zhang et al. 2005). To date, it is difficult to get satisfactory answers by the field study and numerical simulation (Jing 2003, Huang et al. 2013) since the complex factors involved in the mining stability. Therefore, the laboratory studies of stability in the coal strata mining need to be addressed (Kittitep & Decho 2010). Using the geo-mechanics model tests, the rock deformation regularities during the large underground caverns excavation have been investigated (Xie et al. 1995, He 2011, He et al. 2010, Gong et al. 2013). These results are mainly focus on the simulation the stratified rock excavation. However, the paper (Zhou et al. 2006) has discussed the stress distribution characteristics and its variation with the different bedding dip without consideration of the micro-and inhomogeneous structure of rock influence on the entire field stress. The paper (E.T. Ooi & Z.J. Yang 2009) presents an extension of the recently-developed finite element–scaled boundary finite element (FEM–SBFEM) coupled method to model multiple crack propagation in concrete. This paper (Dongwoo 2011) is proposed for simulation of crack propagation in heterogeneous media including randomly distributed voids or inclusions. According to the variation law of stress intensity factors of crack tip I and II in different directions, the new criterion of fracture mode and failure for mixed crack of rock under the compressive loading condition was proposed (Guo et al. 2002). To study the surface crack development and distribution in layered salt rock subjected to the uniaxial compression, the fluorescence and mesomechanical techniques were employed (Li et al. 2011). The paper (Bao et al. 2013) has obtained the surface crack formation mode of layered rock under uniaxial tension by numerical simulation. But the above research cannot reproduce the structure effect of field engineering rock because of the laboratory size in the mode. The large-scale physical model experimental study has been carried out by the State Key Laboratory for Geomechanics

and Deep Underground Engineering (Beijing). And the existing researches are mainly focused on the roadway stability in horizontal layered rock decrypting the infrared characteristics during the rock failure process (He et al. 2010, He et al. 2009, Gong et al. 2013). But the crack propagation and coalescence variation law are rarely seen.

Great number of engineering practice show that large scale physical model experimental is the effective means to reproduce and analyze the stability of coal stratum. Thus, this paper presents the large scale physical model experimental study of the crack propagation during failure process of roadway in horizontal soft rock stratum. The crack formation, propagation until coalescence are all analyzed and the failure mechanism of soft rock roadway are deeply discussed from the crack aspect. All these results are expected to be helpful for the deep recognizing and understanding the law of roadway destruction.

2 MODEL AND EXPERIMENT DESIGN

2.1 *Geological background*

Based on the geological structure of Qishan coalmine in Xuzhou, this paper had simulated the horizontal contacted roadway in north wing track which lied in the depth of −1000 m. This roadway which is the main development roadway has the length of 650 m. To the north, it contacts with −850~−1000 downhill of the north wing track. To the south, it links the −850 downhill of the contacted track. According to the geological profile, the −1000 contacted roadway of horizontal north wing track which is actually the crossing layer roadway passed through 1# and 3# coal stratums three times respectively and 4# coal seam twice. It can be noted that the lithology is mainly sandy mudstone, mudstone and sandstone. The original rock mechanical parameters of the three types of rock mass for the roadway simulation of geological structure are listed in Table 1.

2.2 *Model design*

The 'YDM–C Geological Disaster Simulation Testing Machine', was used to accommodate the physical analogue model and apply boundary loads. The testing machine consists of main stand, hydraulic loading-control system, and data collection system. The test machine was use for two purposes, i.e. roadway tunnel excavations under plane loading conditions and deformation and failure of the underground openings under plane loading conditions.

Based on the original rock mechanical parameters, the author suggested that the similar material could be simplified into the sandstone, shale and coal three physical finite element plate (PFESA) to simulate the geological structure of the practical engineering. This geomechanical model test adopted different plates of five kinds of dimensions and their geometric dimensions and mechanical parameters are shown in Table 2.

2.2.1 *Similarity parameters of model*

The dimensions of the PFESA model were 1600 × 1600 × 400 mm, and the roadway excavation zone was designed as a cubic space with a

Table 1. Main physical and mechanical parameters of engineering rock mass.

Rock mass	Volu-metric weight (kN/m^3)	Compressive strength (MPa)	Elastic modulus (GPa)	Poisson ratio	Friction angle (°)
Sandstone	26.55	63.98	25.77	0.151	33.71
Mudstone	25.78	43.78	21.01	0.127	36.35
Coalseam	13.50	26.15	4.51	0.358	40.07

Table 2. Parameters for basic elementary sheet.

Size (cm)	Simulated rock mass	Ratio of water to gypsum	Volu-metric weight (kN/m^3)	Compressive strength (MPa)	Elastic modulus (GPa)
40 × 40 × 3	Sandstone	0.8:1	14.68	6.75	1.28
40 × 40 × 2	Mudstone	1:1	11.25	4.66	0.94
40 × 40 × 1	Coalseam	1.2:1	8.4	3.38	0.81
40 × 20 × 3	Sandstone	0.8:1	14.68	6.75	1.28
40 × 20 × 2	Mudstone	1:1	11.25	4.66	0.94

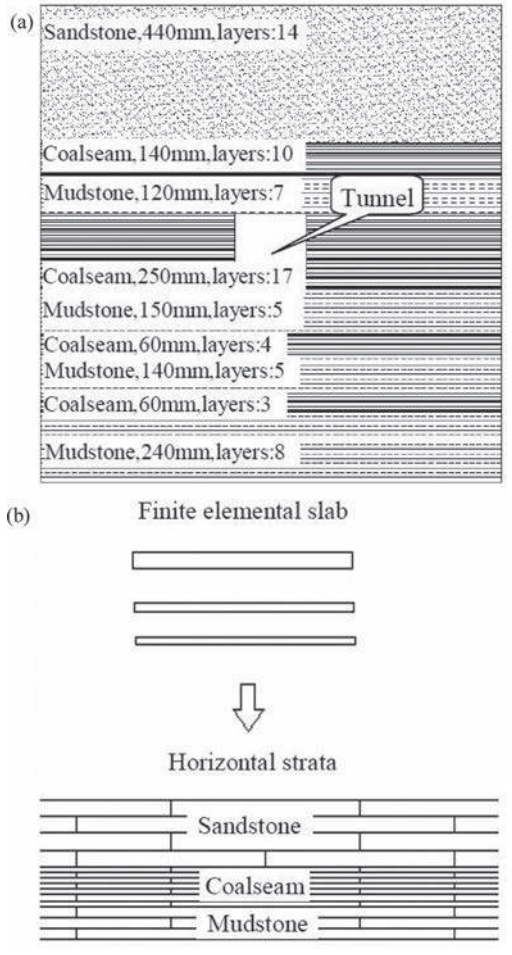

Figure 1. Similarity model; (a) Simulated rock types; (b) Model-making process.

face area of 250 × 200 mm^2 and tunneling length of 400 mm. The geometric scale factor α_t, defined as the ratio of the dimension of the real rock mass to the physical analogue model, was determined as $\alpha_t = 10$. Thus the model can simulate a rectangular-shaped underground cavern with the width of 2.5 m and height of 2 m (see Fig. 1a) and a dimension of the surrounding rock mass of 16 × 16 m, which was the typical configuration and dimension of the underground roadway found in China. According to the uniaxial compressive strength of the real rocks and the maximum loading capacity (5 MPa) of the testing machine, the force scale factor α_σ was evaluated as $\alpha_\sigma = 8$. In addition, for the sake of calculating the body force (i.e. the unit weight, see Table 1), we need to define a body force scale factor α_γ, which can be derived by $\alpha_\gamma = \alpha_\sigma/\alpha_t = 8/10 = 0.8$.

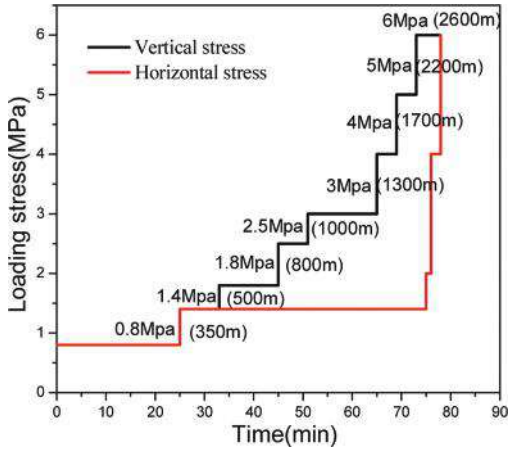

Figure 2. Loading scheme.

These force scale factors were used in the tests for fabrication the artificial materials of the PFESA model (see Table 2). The model is divided into nine layers with the help of the geological column map of Qishan. The lithology and thickness for each layer, number of layers for plate are described in Fig. 1a,b. And the roadway located in the central model.

2.2.2 *Loading design of model*

This experimental design aims at simulating the overload failure mode of roadway under the gravity stress and tectonic stress. First, simultaneously increase the vertical and horizontal loads to the stress state corresponding to the depth of −350 m (both vertical and horizontal stresses are 0.8 MPa). Secondly, load the vertical and horizontal stresses to the state of −500 m depth and keep constant. Then, load the vertical stress progressively for the research on the crack propagation. Last, retain the vertical stress, and then increase the horizontal stress progressively until the total destruction of model to study the effect of horizontal tectonic stress on the failure process of roadway model. Fig. 2. shows the loading curves of roadway.

3 STRESS FIELD DISTRIBUTION

3.1 *Analysis of stress*

Strain gauges were placed at the key point in the surround rocks shown in Fig. 3. Two strain gauges were used at each of the measuring point for capturing straining in the x and y directions respectively. Dense distribution of the gauges was utilized in the near-face region and sparse-arrangement for the far-field region.

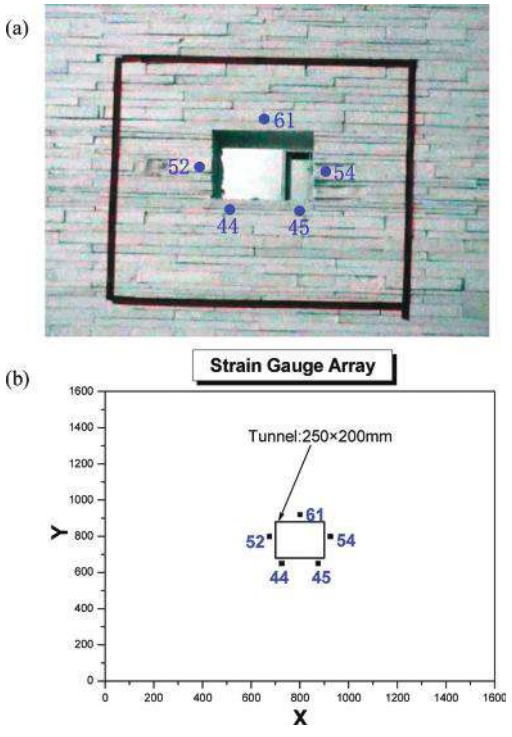

Figure 3. Key point strain gauge array; (a) Physical model; (b) Strain gauge array.

During our test, external stresses were applied in the vertical and horizontal directions which correspond to a quasi-plain stress states. In-plane strains were measured during the tests. The rock stratum is inclined horizontally, thus the vertical and horizontal stresses acted in the beddings can be recognized as the major and intermediate principal stresses. Consequently, the measured strains at each of the point are the major and moderate principal strains under the condition the deformation is pure elastic. Utilizing formula (1), the principal stresses, sigma 1 and 2, can be given:

$$\left.\begin{aligned}\sigma_1 &= \frac{E}{1-v^2}(\varepsilon_1 + v\varepsilon_2)\\ \sigma_2 &= \frac{E}{1-v^2}(\varepsilon_2 + v\varepsilon_1)\\ \tau_{\max} &= \frac{E}{2(1+v)}(\varepsilon_1 - \varepsilon_2) = \frac{\sigma_1 - \sigma_2}{2}\end{aligned}\right\} \quad (1)$$

where σ_1,σ_2 are the maximum principal stress and minimum principal stress in the plane; $\varepsilon_1,\varepsilon_2$ are the strains on the principal stress direction and $\tau_{\max}$ is the maximum shear stress in the plane.

3.2 *Brittle fracture G criterion*

Assume that there is an infinite glass plate thickness of B. After being stretched, Glass plate are fixed on both ends. If the plate subjected to uniform tensile stress, the strain energy stored in per unit volume is: $\sigma_e/2 = \sigma^2/2E$. If cut a crack length of 2a in the center of the plate, due to the crack surface stress disappear, releasing part of the elastic strain energy. At this point, the state of plane stress is: $U = \pi\sigma^2a^2B/E$. On the other hand, surface crack propagation into a new need to absorb energy as follows: $S = 4aB\gamma$, where γ is the surface energy required by forming new surface per unit area and 4aB is the area of the crack surface on both sides combined.

If the strain energy release rate dU/dA (dA = 2Bda) is equaled to the energy absorption rate required by forming new surface dS/dA, crack has reached a critical state, at this time, a slight interference will make crack expands itself, enter into unstable state. If the energy absorption rate is greater than strain energy release rate, crack is stable, otherwise, the crack is unstable. So as to conclusions:

$$\left.\begin{aligned}&\frac{d}{dA}(U-S) > 0, \text{ Unstable}\\ &\frac{d}{dA}(U-S) = 0, \text{ Critical state}\\ &\frac{d}{dA}(U-S) < 0, \text{ Stable}\end{aligned}\right\} \quad (2)$$

where $G_I = dU/dA$ is the strain energy release rate and $G_{IC} = dS/dA$ is the energy absorption rate. Subscript I representative type I crack, the critical condition of the crack is: $G_I = G_{IC}$ (2). Formula (2) is called the brittle fracture G criterion.

4 CRACK GROWTH ANALYSIS

As the vertical stress is loaded to the third stage, the floor heave occurs firstly in the roadway. Then the tensile crack and shear crack appear at the left side of the roadway, continually propagate, converge and coalesce. And shear crack generate at the right side of the roadway afterwards and appear at the top region latest. The critical stress state for the last total destruction of the roadway is 6 MPa of the horizontal stress and 6 MPa of the vertical stress. In the next section, the crack initiation, propagation and coalescence in the floor and left side of the roadway are analyzed respectively. Because of the later occurrence of the crack in right side and roof of the roadway and the little variation, these will not be analyzed in this paper.

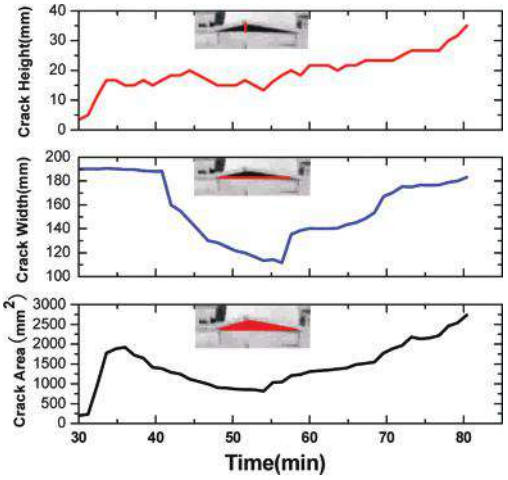

Figure 4. Relation between geometric parameters of crack and time.

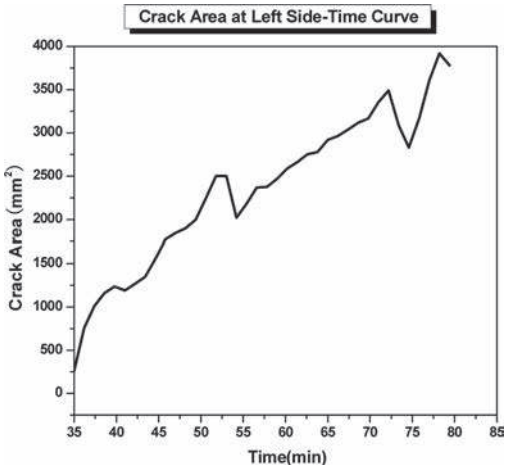

Figure 5. Crack area at left side-time.

4.1 *Analysis of the cracks at bottom of the roadway*

In order to analyze the change process of the cracks which are under sustained loading condition at the bottom of the roadway, in this paper, the length, width and area of the cracks at the bottom of the roadway are measured. Relationship of geometric parameters of crack and time is plotted in Fig. 4.

From Fig. 4, we can conclude that the trend of cracks in the bottom of the roadway as follows: 1) The length of crack is bigger and bigger indicating that the crack has extended along the height direction; 2) The crack width has little change and experience a descent stage. It can be seen that roadway width deformation is obviously in this period. After that, the width increase due to the new crack appearance. 3) The crack area is rising sharply at the beginning, representing the produce process of crack, then the area retain stable. And the descent stage is the result of fracture of gypsum plate. Last, the area is steadily rising indicating the overall crack area is being larger.

4.2 *Analysis of the cracks at left side of the roadway*

In order to analysis the change process of the cracks which are under sustained loading condition at left side of the roadway, the area of the cracks in the left side of the roadway are measured. The crack area-time curve is shown in Fig. 5.

From Fig. 5, we can obtain the trend of crack at left side of the roadway as follows: Crack area has an ascendant trend as the whole except slight fluctuations. With the increase of load, three tension cracks sequentially appear at the left of the roadway. With the experiment performing, cracks continually propagate, converge and coalesce until the left side wall of the roadway collapsed. Large stress accumulation in the model is generated due to the friction between the rock layers movement at the left side of the roadway.

5 CONCLUSION

1. With increase of the roadway depth, the left side and the right side of the roadway are subjected to tensile, shear, or combined stress state. Thus, tension crack, shear crack or mixed mode crack are existed in these locations.
2. During the failure process, floor heave appears first in the roadway tunnel. Propagation of fractures leads to the further development of the floor heave. It indicates that the floor is weaker than the sides of the roadway in horizontal strata.
3. Under the increase of loads, there are three independent tension cracks firstly arise on the left side wall. As further increase of the loading, cracks continually propagate, converge and coalesce leading to the penetrating cracks on both sidewalls and the floor until complete failure of the roadway.

Research on the performance of foam agent used for mine fire prevention

Zhao-Jun Tian, Xiao-Lu Zhang, Rong-Yi Zhou & Qing Ye
School of Energy and Safety Engineering, Hunan Province Key Laboratory of Safe Mining Technology of Coal Mine, Hunan University of Science and Technology, Xiangtan, Hunan, China

ABSTRACT: Foam agents have been widely applied to mine fire prevention, and its performances determine its using effects and economic benefits. This paper explored the mechanism of foam formation and rupture as well as parameters of foaming properties. Many factors that could exert influences on the foaming performance and the foam stability were discussed, such as foaming agent itself (the concentration, the kind and its molecular structure), mixed surfactant, salt, temperature, pH, surface-active nanomaterial and polymers, and some methods were put forward to improving the performance of foam agent.

1 INTRODUCTION

Foam fire prevention technology has been applied to mine fire prevention for more than fifty years. Its mechanism is that the heat taken away through the evaporation of foam could reduce the heating rate of coal and the generated water vapor would isolate the oxygen existing in the environment. The coal spontaneous combustion is the main factors of mine fire, accounting for the total of 85%–90%. To address this problem, domestic and foreign scholars have conducted a lot of researches. Three-phase foam, containing solid, liquid, gas material, developed by China University of Mining has been applied to many mines. The results of application indicated that the process was simple, the effect of fire prevention was obvious, and foam could stack up to a sufficiently height to prevent the continuation of temperature at high fire point. The gel foam setting gel and foam with excellent properties of fire prevention in one has high foam stability and foam ductility.

However, foam performance is still not well meet the actual production. The stabilization time had only 8–24 hours, and its life cycle could hardly satisfy the demand. Thus, raw material had to be pumped into frequently. The gel foam also has its own shortcomings. For example, it requires foaming agent possess excellent performance to reduce production costs and expand its scope of application. The improvement of the foaming performance of foaming materials not only can drop the cost, but also increase the volume of foam per unit time. All of these could be conductive to applying the accumulation and scalability of foam material more effectively. Thus, it is of great significance to improve performance to promote the application of fire prevention and improve its performance in mine further.

2 MECHANISM OF FOAM GENERATION AND RUPTURE

When pumped gas into or stirred, the aqueous solution containing surfactants can generate bubbles wrapped with film. The surfactants are distributed on the internal and external surface of film. Surfactant molecule is a kind of amphoteric molecule, which contains both hydrophilic groups and hydrophobic groups at the same time. Its hydrophobic hydrocarbon chains spread into the gas phase and hydrophilic polar groups insert into water. In virtue of high gas volume fraction, bubbles could float above water spontaneously, contact with air, and then stack up on the surface of liquid to form foam. To maintain its mechanical stability, the foam generally is rendered as polyhedral shape. It is a dispersion of gas dispersed in liquid, belonging to unstable system thermodynamically. And it has more free energy than the sum of air and liquid. As a result, the foam will break down and the total free energy of the system reduces. The rupture of foam is mainly caused by the drainage when the gas defuse through membrane, the gravity and the difference of pressure at each point in the film.

3 PARAMETERS OF FOAM PERFORMANCE

Parameters of foam performance mainly include the foaming performance and the foam stability. Foaming agent is a kind of surfactants with excellent foaming performance. It can reduce the surface tension of aqueous significantly and make it easier to produce foam. Generally, the ability of reducing the surface tension is used to represent the foaming performance of agent. The stronger the ability is, the better foaming performance present. But it is not on the contrary. The formation of foam is a dynamic process, accompanying with the rupture. Therefore, good foam stability can not only increase the amount of formation, but also improve the quality. It is an important prerequisite to improve foaming performance. At present, many scholars are keen to improve the performance indirectly by improving the foam stability. The surface viscosity and the surface flexibility are main factors affecting agent foam-stabilizing properties. The former, which can be used to measure the ruggedness of adsorption film, is produced by monolayer composed of active molecules on the surface. Because the ruggedness determines the film strength, the viscosity will affect foam stability. The latter could restore the film thickness to promote its stability when foam suffer from mild local impact and prevent film from.

4 FACTORS AFFECTING FOAM PROPERTIES AND WAYS OF IMPROVING FOAM PERFORMANCE

4.1 *Foaming agent own factors*

Foaming agent own factors is the fundamental factor affecting foam properties, mainly in the type and the concentration of the foaming agent and the molecular structure.

4.1.1 *Types and concentration of foaming agent*

The performance of different foaming agent varies. It is mainly related to the nature of its own, such as some special groups and its adaptability to the external environment. Foaming agent concentration also exert influence to foaming properties. When the concentration is less than the critical micelle concentration(cmc), the increase of solution concentration will increase the adsorption capacity, reduce the surface tension and enhance the foam strength. But the stability of formed foam is poor. When the concentration is above the cmc, the surface tension can't be reduced by increasing the concentration, but increase slightly. However, the solution surface will form increasingly dense film because of the enrichment of foaming agent. Thus, the stability of formed foam increases. When the concentration is continued to a certain extent, the foam liquid content will be reduced and the fragility of film increases. As a result, foam become more unstable.

3.1.2 *Molecular structure of foaming agent*

The increase of carbon chain of foaming hydrophobic groups within a certain range could enhance the cohesive force among the molecular chains, which makes the interface of film have greater flexibility and stronger mechanical strength. However, when the carbon chain continues to increase, the foaming power will be reduced. For the long carbon chain hardens the film and reduces its flexibility. The hydration of agent hydrophilic groups could form a very thick water film around itself, which turns free-flowing water into bound water with poor mobility. As a result, it increases the viscosity of the liquid film, slows the rate of thinning liquid film owing to gravity drainage and stabilizes the foam stability. Therefore, foam stability can be improved by the addition or deletion of the length of carbon chain. Generally, strong hydrophilic groups matched with suitable hydrophobic groups can be used to produce a better foaming agent.

In addition, part of the hydrocarbon chain can be also replaced by some special reactive groups to obtain some outstanding properties original structure do not have. Aydogan put forward a novel asymmetric Bola surfactant-FHUB through replacing part of hydrocarbon chains by fluorocarbon chains with strong rigidity. This substance has strong hydrophobic and oleo phobic. The aggregation ability, the mobility and the dispersion coefficient is also good. Such surfactants are not very sensitive to changes of ion concentration existed in solution. Besides, the grows of fluorocarbon chain could lead to the reduction of limit surface tension and the increase of Krafft and cmc. Therefore, it can greatly improve the foaming performance and the foam stability.

4.2 *Mixed surfactant*

It is a common means of improving foaming properties by compounding surfactants. On the one hand, owing to the intermolecular interactions, the electrostatic repulsion between polar groups decreases and surfactant molecules will be arranged more closely. On the other hand, hydrocarbon chains would attract each other because of the hydrophobic effect. Therefore, it is easier for surfactant molecules to aggregates to form micellar in the interior of solution, and surfactant molecules are arranged more closely and have a greater adsorption capacity in the surface adsorption layer. Those surfactants synergies can not only increase foaming

performance and foam stability significantly, but also reduce the cost of the surfactants and the damage to the environment. Therefore, there is profound significance and broad prospects in improving economic efficiency and popularization.

There are some common complex systems, such as anionic/anionic, anionic/cationic, anionic/amphoteric, anionic/nonionic, male/non-ionic mixed surfactant and so on. Compared with other combinations, anion/cation, anionic/amphoteric show a better synergistic effect.

4.2.1 *Anionic/Cationic mixed surfactant system*

Recent studies negated the prospective that the negative effect produced by anionic/cationic mixed surfactant system would result in loss of surface activity. Instead, they found that these systems had good foaming capacity and low surface tension. The electrical interaction between the two surfactants reduces the effectiveness and the efficiency of the surface tension as well as the critical micelle concentration of the system, increase the adsorption of active agent at liquid surface and the strength of film, Improves the stability of foam, and increase the foaming height, which showing a significant synergistic effect. During tests of SDS/OB-2 composite system, Chen Weizhang found that the foaming height increased rapidly with the addition of OB-2 and reached the maximum height at 245mm when (SDS): m (OB-2) was 1:3. Similarly, SDBS/OB-2 composites exhibited a good composite effect also. Minimum value of the surface tension was 2312mN·m-1 and maximum foaming height was 214mm when m(SDBS):m(OB-2) was 2:1.

4.2.2 *Anionic/amphoteric mixed surfactant system*

Amphoteric surfactants have some advantages, such as low irritation, good resistance to hard water, excellent biodegradability, etc. Regrettably, its price is too expensive. In the anionic/amphoteric mixed surfactants system, cheaper anionic surfactants not only can be used to replace amphoteric surfactants, but also compensate for shortcomings of anionic surfactants. As positive charges exist in amphoteric surfactant molecules, there is a strong electrical interaction between anionic surfactants and amphoteric surfactants and display an excellent synergy and great practical value.

4.3 *Polymer*

Numerous studies results showed that there were significant interaction between polymer and surfactant. The surface tension of ordinary polymer/surfactant mixture solution is often higher than singles. The reason is that part of surfactants are adsorbed by polymer and the concentration of free surfactant in solution drops. After polymer are added into the agent, the mechanical strength of foam film enhanced through increasing the viscosity of liquid phase on the one hand. On the other hand, the polymer can slow down the liquid expulsion rate and the film thinning speed, increase the apparent viscosity of the liquid film, and make the foam film more flexible. Besides, the coadsorption of foaming agent and polymer molecules on gas/liquid interface make the solution more tenser and increase the the draining period and the stability. Therefore, the polymer plays the role of foam stabilizer. By observing changes of the bulk viscosity and the surface tension of mixed solution, the interaction between polymer and surfactants can be studied. Du Jianfen conducted comparative experiments to analyze DP-4 foam performance under high temperature and pressure. Single and composite foam system and the system with the addition of 2% crude on the basis of original were researched in this study. He came to the conclusion that composite foam system with polymer had better foaming capacity and foam stability than single system without polymer. In addition, the polymer concentration was another important factor affecting foaming performance. When the concentration was too high, the film thickness could not be restored; while the concentration was too low, the self-repairable ability and foam stability of film became poor because of low elasticity.

4.4 *Inorganic salts*

In the practical application, various salts inevitably exist in the aqueous solution of foaming agent. Generally, the performance of Ionic surfactants is susceptible to electrolyte while it is not for non-ionic surfactants. As for ionic surfactants, the adsorption of agents can be increased significantly when a certain amount of inorganic electrolyte was added into solution. The reason is that increasing the concentration of inorganic ions appropriately makes more counter-ions permeate adsorption layer. And these ions would combine with ionic surfactant molecules, weakening the electrical repulsion between surface-active ions. Then, adsorbed molecules are arranged more closely. However, when the salt concentration is too high, it will compress the diffuse double layer. These changes weaken the electrostatic repulsion between surfaces and make the film more easier to thinning and rapture, which exert negative impact on foaming performance. A study certificated that the half-life of foam had nearly doubled when the NaCl concentration was 0.0125% than those without salt. Nevertheless inorganic salts began to play a serious negative role on foam stability after the NaCl concentration reached at 0.1%.

4.5 *Temperature*

Wang Xianguang tested the foam properties of SDBS (Sodium dodecyl benzene sulfonate) and three kinds of ABEPS (Alkyl benzyl group of homogeneous polyoxyethylene ether sulfonate) at different temperatures in experiment. The data showed that the foaming performance of surfactant solution would be improved with the rising of ambient temperature, while the foam stability was declining. Within the appropriate range, the foam temperature is conducive to reduction of the surface tension, which increased total area of film formation in unit time and enhanced the foaming capacity. As the temperature continued to rise, the evaporation and the discharge of water film quickened, which thinned the film and reduced solution viscosity. On the other hand, the increased molecular motion and the thermal expansion of gas volume also thinned the film. In addition, elevated temperature reduced the hydration of hydrophilic surfactant molecule. Meanwhile, the reduced cohesion between hydrophobic carbon chain and repulsion between film weakened film strength. Taking all factors, the foam stability decreased.

4.6 *pH*

Liu Zhaowen studied the effect of pH on foam performance with certain complex systems, and found that the pH had a great impact on the forming properties. Under acid conditions, the foaming capacity of complex systems was weak. As the pH increasing, the foaming capacity enhanced and reached maximum at pH 7. However, it presented in the opposite under alkaline conditions. Zhang Qun studied the forming capacity and form stability of different varieties of oleic acid solution at different pH. They found that the capacity was very weak when pH<7, then gradually increased with the increase of pH when pH>7, and achieve the finest effect at pH 10. Other experiments showed that the change of PH values have few effect on foam properties of non-ionic surfactant solution. However, it affected the foam stability of ionic surfactant aqueous solution greatly. The effect of pH on foam varied with the composition of the solution. The main cause is that the change of pH affects the force between active substances or between active substance and water. In practical application, the value of pH should be adjusted to a reasonable range based on the degree of sensitivity to pH about that system.

4.7 *Surface-active nanoparticles*

Some surface-active nanoparticles with suitable hydrophilic-lipophilic properties can be adsorbed at the air/liquid interface, forming monolayer or multilayer particles which is similar to surfactant adsorbed monomolecular layer. This structure can stabilize the gas/liquid phase and play the role of foaming and stabilizing foam. Binks obtained a stable foam system with silanized SiO_2 particles, and improved the foaming performance and foam stability greatly by adjusting the hydrophobicity of particles with the use of NaCl. Cui Yanzhen conducted a comparative experiment targeted at nano calcium carbonate—surfactant mixed system. When different concentrations of SDS were added into 1% dispersion of nano-$CaCO_3$, she found that instant foam volume increased with the increase of the SDS concentration and the effect was more pronounced than single SDS system. When the SDS concentration range is lower than the cmc, the foam volume of mixed system is also lager than single system. Apparently, nano-$CaCO_3$ with SDS produced a significant synergistic effect in foaming and foam stability.

5 SUMMARY AND OUTLOOK

In summary, the performance of the foam material was affected by many factors, such as foaming agent characteristics (the concentration, the kind and its molecular structure), mixed surfactant, salt, temperature, pH, nanomaterials with surface activity and polymers. We should consider to seek ways to improve foam performance according to the mechanism of these effects of factors, and make full use of all the advantages of foam in the field of fire prevention, such as simple preparation, low cost, few resources consumed and so on. It is proved to be an effective way to improve the effect of coal spontaneous combustion. In addition, we can mix it with other fire prevention material, included nitrogen, sediment and gel to make a mixture. Not only can it save resources, but also it is of significant economic value for its better fire prevention performance than single material.

Research on efficient dust suppression measure in full-mechanized mining face

G.J. Yi, M.X. Jia, J.H. Wang & S.M. Wang
China University of Mining and Technology (Beijing), Beijing, China

ABSTRACT: Aiming at the actual situation of #131419 fully mechanized face, testing in the field and analyzing the problems in the fully mechanized face, including water quality, nozzles, coal shearer's spray and dust reduction system, closing between the hydraulic support, finding the reasons for large dust concentration. From system point of view, the author improves the original dust suppression, uses the new engineering and technical measures, including magnetized water, changing material of nozzles, optimizing the spraying system for coal shearer, closing dust source between the hydraulic support and so on, finally uses the new efficient dust suppression measure in #131419 working face of Laowuji Coal Mine with on-site detection, make the conclusion finally: by taking the new efficient dust suppression measure, the dust suppression efficiency of working face is more than 80%, especially the respirable dust is greatly reduced and the workers exposed dust is reduced.

1 INTRODUCTION AND BASIC SITUATION OF THE WORKING FACE

At present, the attention degree of most mines for underground dust prevention is not enough, the dust control engineering techniques is relatively single, resulting in that the dust concentration seriously exceeded the national standard. On the system level, through the analysis of the existing problems in the system, this paper puts forward some improvability measures for the existing dust removal system in Laowuji mine #131419 working face, including engineering technical measures, such as the use of magnetized water, selecting new nozzle, improving coal winning machine internal and external spray system, optimizing frame dust source closed systems and so on. On a whole, the underground coal dust is under control, the dust concentration of fully-mechanized face is greatly reduced, and the working environment of work face is improved.

The maximum trend length in #131419 of Laowuji Coal Mine is 1053 meters, the minimum trend length is 1030 meters, and the average trend length is 1042 meters. The thickness of mineable coal averaged at 2.8 meters and the dip of the coal averaged at 10°. The capability is 1.5t/m^3.

The coal mining method in #131419 is the strike longwall retreating method and the coal mining technology is Coal Mining Technology, which uses the ZY3300/15/28 Hydraulic Support at the same time the MXG-250/600QWD Double Cylinder Shearer.

The Mining Face uses SGZ730/400-type scraper conveyor, the roadways and transportation lanes use SGW-40T-730/110 Crossheading Conveyor as well as STJ-800 Belt Conveyor.

The #131419 working face adopts dynamical pressure water infusion in exploitation process to prevent dust, uses ZYG—150 which total weight is below 2 tonnes, hole diameter is 75 mm, the drilling length is greater than 50m, drilling machine drilling in the upper and lower roadways meanwhile seaming water infusion bi-directional.

2 LAYOUT OF TEXT PROBLEMS IN ORIGINAL DUST REMOVAL SYSTEM

The respirable dust concentration of the #131419 work surface in the working environment is more than 10 mg/m^3, at the same time, the maximum concentration of respirable dust appears at 5 meters after advancing support, reaching at 129 mg/m^3. In addition, near the shearer and the upper and lower end, the concentration of respirable dust averaged at more than 20 mg/m^3 which is great harm for workers. The reason producing such a large amount of dust, after analysis and experimentation, is that the original dust removal system exist the following problems.

2.1 *The problems of water*

All tables should be numbered with Arabic numerals. Headings should be placed above tables, left justified. Leave one line space between the heading and the table. Only horizontal lines should be used

within a table, to distinguish the column headings from the body of the table, and immediately above and below the table. Tables must be embedded into the text and not supplied separately. Below is an example which authors may find useful.

2.2 *The problems of nozzle*

Due to using traditional materials-brass nozzle in #131419 working face, this type of spray nozzle are likely to cause destruction of the surface material owing to high velocity flow erosion and corrosion in the process of using, which make nozzle increase the amount of water but decrease the degree of spray.

2.3 *The problems of spray and the dust reduction system for coal*

Coal mining machine uses MG700 series of spray and dust reduction system for coal, the Interior Spray System comes with appliances, which is fixed inside the coal machine fuselage, whose nozzles are relatively settled, and the water pressure is lower (1~3MPa), in a word, the efficacy of actual removing of dust is just so so. The nozzles in External Spray System put direct jet to use, the water is not completely atomizing, which waste much of water and in contrary, the effect of dust removal is reduced.

2.4 *No closing between the hydraulic support*

Supporting of hydraulic support in Full-mechanized Mining Face is a major source of dust and moving hydraulic support often can cause a grate deal of dust for supporting process. The #131419 working face does not do enough protective measures for dust falling in this respect, which results in the dust concentration rising rapidly. After measured, the highest concentration of respirable dust appears at 5 meters behind moving hydraulic support and can reach for 129 mg/m^3.

3 OPTIMIZATION IN DUST-FALLING SYSTEM

Aiming at the original dust-falling system problems, the author has improved the original system by doing experiments and determining in the locale, at last, the author put forward specific measures as follows.

3.1 *Using magnetized water to reduce dust*

In order to solve the problem of water quality, the author does experiment of magnetized water to reduce dust in the laboratory, noticing the water of coal-water surface tension and contact angle changes which are shown in the following Figure 1 and 2.

By the figures we can know, the surface tension of water continue lower when the magnetic field intensity is between 0.5–0.7T, at the same time, the water is more easy moist coal and spray dust; the water-coal contact corner is linear decrease when the magnetic field intensity is between 0.6–1.2T and the law is obvious; the water-coal contact corner is reach for the minimum number 29.2° when the magnetic field intensity is 1.2T, that is reduced by half and has obviously effects.

By the magnetic experiments, we decided to use permanent magnet to magnetize the water considering both cost-effectiveness and security performance in #131419 working face. The permanent magnet was made up of two magnets whose diameter is 100mm and thickness is 15mm; we can figure out that the magnetized pipeline's length is 2 m based on the water's velocity and the time of magnetization.

In addition, it is important that the water should be filtered in underground first before magnetized. The reason is that if the water is filtered in the ground and then transported to working face by pipeline, in this process, there may produce other impurities which could reduce the fog effect.

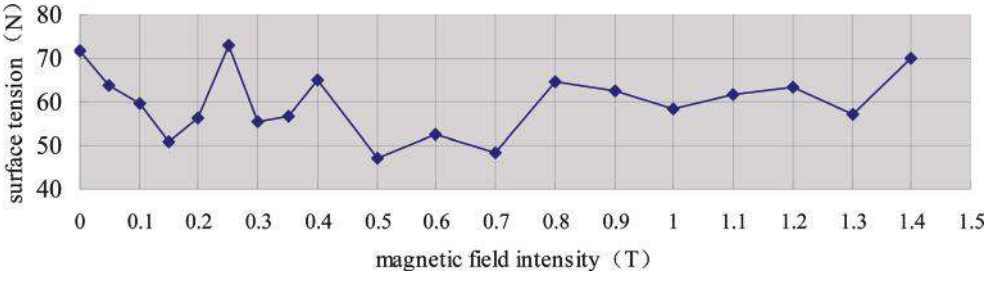

Figure 1. The relationship between surface tension of water and magnetic field strength.

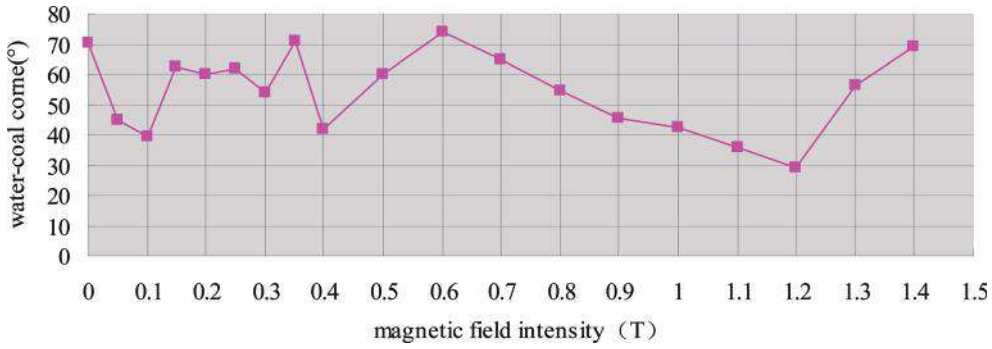

Figure 2. The relationship of coal water contact angle and the magnetization strength.

3.2 *The improvement and arrangement of nozzles*

Having done with the things above, then what we should do is improving the original nozzles in the system. The working face was using copper material nozzles which have several defects. In contrast, ceramic material nozzles have other advantages such as strong corrosion resistance capability, abrasion resisting, high strength, hardness and other advantages, so it can perfectly overcome the defects of copper material nozzles. After detecting in site, the author decides to use ceramic material nozzle whose aperture is 1.5 mm.

After determined the material of nozzles, and then we should optimize the arrangement of nozzles which influences a lot on the effect of spraying dust. Only when the nozzle's spray wraps up totally the shearer drum, can the spray dust spray dust results. Therefore, the principle for the arrangement of nozzles is that the nozzle's spray wraps up totally the shearer drum. In #131419 working face, after repeatedly experiments, we install 3 high pressure nozzles on each spray device which are mutually staggered. The water can be formed fog flow screen when it arrives at the coal shearer's drum and totally cover dust source. In order to control maximized of shearer cutting coal dust, the nozzles should point to the shearer's gear and keep an appropriate distance. According to the actual condition of the underground, the spray device is welded on the shearer traction motor parts to ensure the water-fog can be blowed to the dust source from time to time.

3.3 *The improvement of the spraying for coal shearer*

The author introduces the optimizations for spray and nozzles; here we introduce the improvement of the spraying for coal shearer. According to the actual circumstances, there exists lots of problems on the outer and inner mist spray at the coal shearer in the working face, such as low spray pressure and others. The authors do the following optimization for the spray device of coal shearer.

1) The improvement of internal spraying device
Because the water's pressure of water pressure is low, firstly we should increase the pressure of the water. The larger water pressure is essential to ensure the effect of spray. Secondly, we should increase the number of filtering of the water and setup several different precision filters along the liquid pipeline to ensure the quality of water and to prevent the spray nozzle clogging at the same time.

2) The improvement of external sprayer device
The improvement of external sprayer device in coal mining process is the main force to spray dust system in the working surface, so we do more improvements for it. The improved high-pressure shearer spray of dust reduction system contains water filtration system, booster pump, pressure reducing valve, coal shearer with high pressure spray device, as shown in the following Figure 3:

1. The water filters with high performance multilayer coagulation has better effects. The impurity filtering accuracy is below 1.8 μm and the filtering speed is between 0~100 L per minute and the working pressure is 0.3~2.5 MPa. The water filters installed in the water supply pipeline, which can filter water as well as protect booster pump.
2. The supply of high pressure water and spray system is the key technology to high pressure spray dust in coal mining machine. This system uses TQB80/12–5 booster pump whose quantity of flow is 80L per minute and pressure 0~12.5 MPa. The booster pump is installed on the shearer, the low-pressure water is changed

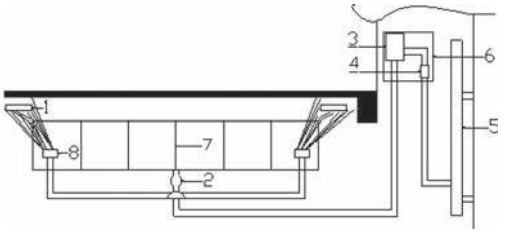

Figure 3. Shearer' high pressure outside the spray dust suppression system.

into high-pressure water through the filter and then delivers to the coal shearer sprayer device to produce high-pressure spray.

3. The system uses Y42X pressure reducing valve whose nominal diameter is 25 mm and adjustable pressure ranges 1.6~10 MPa. The working principle is that the pressure changes through throttle valve. The inlet pressure can be reduced at the outlet, when the quantity of flow and pressure change, the water can keep stable due to its media power. In order not to influence the water pressure of coal shearer, the pressure reducing valve is installed before water pipeline.
4. The high pressure spray device adopts single hole nozzle which has a far range, big flow and high degree of atomization. High pressure water spray can surround the head of the coal shearer with the help of cohesion, intercept and diffusion effect of water spray to reduce dust. In addition, a high concentration of fog particle has the effect of filtering working surface to air flow, which, to some extent, purifies the working surface wind.

In order to meet the field conditions, we do the tests repeatedly and find that the spray effect reaches for maximum effect when the high pressure of the system is 4.0 MPa and quantity of flow is 12.24 L per minute. The effective range of the system is 2.85 meters and the maximum range can reach for 3.8 meters.

3.4 *The arrangement of spray point in the working face*

Above are improvements respectively of spray water, spray nozzle and outer and inner mist spray at the coal cutter, next the spray system only has the last step of work, namely reasonable layout of the spray point when the shearer is on work. The coal cutting speed of shearer in the #131419 face is 6m per minute, the center spacing of stents is 1.5m, so the time that the shearer required to pass through each bracket is 15s, therefore, fully mechanized mining face live stent spray can layout in the following manner:

1. When the shearer cuts coal upstream, NO. 4, NO. 9 and NO. 14 spray device on leeward side of the coal miner driver spray tracking the shearer, the spray time is 30s. When the shearer walk through a stent distance, NO. 4, NO. 9 and NO.14 on the downwind side of the original coal miner driver has been spray for 15s. At this time, NO. 3, NO. 8 and NO. 13 on the downwind side of the original coal miner driver began to spray; spray time is the same as 30s. Along with the shearer, the stent spray opens one by one.
2. When the shearer cuts coal downstream, NO. 5, NO. 10 and NO. 15 spray device on the leeward side of the coal miner driver tracking the shearer, the spray time is 30s. The circulating mode is the same as above.

3.5 *The improvement of closed system among hydraulic support*

There is not too many protection measures in this aspect in #131419 working face which result in the dust concentration increases rapidly when moving the hydraulic support. According to measure, the concentration of respirable dust is highest after 5 meters of moving hydraulic support and is up to 129 mg/m^3. In order to reduce the amount of dust when moving hydraulic support, the author has done experiments of closed system among hydraulic support to dust source in #131419 working face.

(1) The material of closing dust source between hydraulic supports. According to the performance of hydraulic support, the field conditions and industrial reality also satisfied the closed material characteristics to dust source. The original materials have been chosen as follows: a tank chain sheet structure made of zero copper; knitted rubber rope net structure; high elastic fibers (spandex); high elastic bandage; a rubber band, rubber (board).

Through the market survey and feasibility analysis, we decide to use rubber, rubber wire with the elastic bandage and spandex fabric as elastic material to the closed device. It is seen from surface, there is a great difference between various materials, rubber has several features such as good elasticity, good sealing, no net export, but easy to tear, and the performance would reduce when adding flame retardant. At the same time, elastic bandage resists tearing, easy installation, easy to add conductive wire, but the flame is not good and the dust effect is not good. It is very difficult to find the appropriate size of the loom in the testing phase.

By collecting the related information widely on the elastic material exploring in-depth on domestic rubber industry and textile industry, we preliminarily determine using rubber, rubber thread, and

spandex. Based on understanding of domestic rubber and textile industry technology, through laboratory experiments, including the determination of stress-strain properties, tensile fatigue properties, electrical properties, abrasion resistance and flame retardant properties, and finally we choose the elastic rubber silk bandage material as the appropriate closed material.

(2) The design plan for closed system among hydraulic supports. The material for dust separation is made of high elastic bandage and iron clamp assembly. The performance of closed dust source device demands high standard on chemical and physics performance such as strength, elasticity, flame retardant, antistatic, and corrosion. According to the factors of low temperature underground, humid conditions and the motion characteristics hydraulic support, the high elastic bandage was preferred to as dust prevention materials. The high elastic bandages are made into trapezoid whose length is between 1.6–2 meters. At the same time, in order to avoid the punch local shear connection of the bandage and angle iron too much, ensuring the closed dust source device durable, these were connected by the iron clamp. The iron clamp can wrap the bandage edge that can avoid stress concentrating in a vulnerable area, and can transform it into the edge with the bandage iron clamp of the shear stress, to enhance the service life of apparatus.

4 EFFECTS OF OBSERVATION

The improved measures were applied in the fully-mechanized face, the dust removal effect of the working face was observed, as shown in Table 1:

Through observation, after the #131419 working face adopted the optimized dust removal system, the efficiency of reducing dust reached 80%, while using the traditional dust removal methods, such as ventilation and dust control, could only reach about 40%, so the optimized dust removal system can better improve the working environment, and it could be more beneficial to the health of workers, and provide guarantees for the safety production of coal mine.

Table1. Comparison of before and after optimization.

Position of the observation	The original concentration/mg·m^{-3}	The optimized the concentration /mg·m^{-3}	Efficiency of dust-fall/%
The unde end of face	16.44	3.32	79.8
10 m away from working face	16.84	3.54	78.9
Face site of shearer driver	58	11.58	80.0
The upper end of face	22.04	4.39	80.0

Risk analysis of 18 kinds of coal spontaneous combustion at Huanghua port

J.S. Zhang, S.M. Wang, X.L. Zhang & H.Q. Xiong
China University of Mining and Technology (Beijing), Beijing, China

ABSTRACT: In order to select 6 kinds of coal which are large spontaneous combustion tendency used in experimental study and analysis of the storage in the 3nd silo at Huanghua port, storage coal evaluation modal is established to compare the spontaneous combustion tendency of all 18 kinds of coal. The results show that properties indicators suitable for the quantitative analysis are selected from many factors that influence the coal spontaneous combustion, establishing evaluation system to analyze the storage coal tendency of spontaneous combustion at port; the 4 selected coal internal indicators can be used to establish fuzzy evaluation factors and then evaluation degree of coal spontaneous combustion; the 6 selected kinds of coal are suitable for storage in the 3nd silo and provide support for the experimental study and security storage period calculated in later.

1 INTRODUCTION

Huanghua port has completed 3nd silo construction of the coal storage system. Compared to the yard storage, silo closure and low heat dissipation are more likely to appear high temperature. This requires to explore the coal's which are stored in silo oxidation process and safety storage measures. Beause Huanghua 3nd siol are the largest group of coal storage system now, and can draw lessons from foreign related case is less, given the above situation, we need to select the appropriate coal used in experimental study and analysis.

Now some researchers studied on the tendency of coal spontaneous combustion which occur in goaf (Cao 2009, Shi et al. 2001, Lu & Geng 2009, Yu et al. 2004), mine(Ding & Di 2005) and coal mining working face(Deng et al.2011). Methods including Grey Relational Analysis (Wu et al. 2011), Grey Slope Relational Analysis (Jin et al. 2012), Fuzzy Evaluation (Ding & Di 2005, Deng et al. 2011, Zhou & Qi 2011) and so on, but little research for storing coal's comparison of spontaneous combusion tendency, and there do not have a unified, comprehensive evaluation indicator system. Taking into account tendency of coal spontaneous combustion cotains some vague, ambiguous terms, this paper which combines academic study and practical experience in the production establish an evaluation indicator system of Huanghua port's coal, and then vague comprehensive evaluation model on the tendency of those coal spontaneous combustion to select 6 kinds of suitable coal. The method combines with the characteristics of coal to determine the indicator weight and to ensure scientific and accuracy of evaluation conclusion through the fuzzy calculation.

2 ANALYSIS ON SPONTANEOUS COMBUSTION

2.1 *Coal introduction of Huanghua port*

A total of 18 kinds of coal at Huanghua port, mainly contains Low ash coal, Shenyou series coal, Waigou series coal, Meager lean coal and Shenhun series coal, in those coal, Waigou series come from collaborative coal mines, while others from coal mine which belongs to Shenhua group.

2.2 *The influencing factors of storage coal spontaneous combustion*

This paper studies the size of storing coal spontaneous combusion tendency at Huanghua port, so external factors are not taken into account. Based on the mechanism of coal spontaneous combustion (Wang 2007), The internal factors of coal spontaneous combustion are the metamorphic degree of coal, the composition of coal rock, the sulfur content in coal, the particle of coal, the pore characterisitic, the degree of crushing, the gas content in coal and the moisture content (Wu et al. 2011, Wang 2007). Now analyze the effect degree of different factors on coal spontaneous combustion.

1. The sulfur content in coal. Sulfide majority of pyrite in coal, the chemical equation in burning of sulfide and element sulfur is:

$S+O_2 = SO_2$

$4FeS_2+15O_2+2H_2O = 2Fe_2(SO_4)_3+2H_2SO_4$

Both of those chemical reaction equations are exothermic reaction, and when the products meet water, they will combine with strong oxidizing acid and release large amounts of heat. A huge amount of thermal accelerate the speed of coal oxidation, thus promote the spontaneous combustion. The study found that under the condition of the same coal property, the higher sulfur content, the easier oxidized(Wen et al. 2011).

2. The grade of coal. Coal grade indicates the metamorphic degree of coal, commonly said by volatile content. The lower the coal quality, the higher the content of volatile, while at the room temperature oxidation of coal are mainly depends on the content of volatile. According to the observations and statistics, even under the same conditions of open storage, taking incidence of spontaneous combusion into account, high volatile content coal is twice bigger than low volatile content coal (Wang 2004).
3. The moisture content in coal. How much moisture content in coal on the influence degree of the coal spontaneous combustion are different. Lab studies have shown that when the moisture in coal is lower than 12%, the moisture will produce wet heat to promote spontaneous combustion, but when the moisture in coal more than 12%, due to large amounts of water evaporation remove heat and spontaneous combustion tendency decline (Wang 2004, Zhou & Wen 2009). The Huanghua port coal moisture is greater than 12%, so the moisture for this port of coal spontaneous combustion is suppressed.
4. The ash in coal. The coal ash is a residue when coal sample complete combustion under prescribed condition. It is an important indicator in the study on the characteristics and utilization of coal quality. Coal ash can reduce coal oxidation heat per unit of mass, while the higher the coal ash, the lower the effective yield of carbon, then the more difficult to spontaneous combustion of coal.
5. The particle size of coal. As can be seen from the port date in Table 1, the particle size of 18 species coal is roughly same in Huanghua port. So the effect of particle size are the same on all coal spontaneous combustion at Huanghua port, hence this factor can disregard.

Moreover, the gas content in coal belongs to the nature of coal rock, but research object for the port storage of coal in this paper, so don't consider the influence of the coal gas content in coal spontaneous combustion.

3 THE ESTABLISHMENT OF EVALUATION SYSTEM

Fuzzy comprehensive evaluation method which based on fuzzy mathematics is a method of quantitative evaluation. According to the features of Huanghua port and characteristics of storage coal, through the selection of evaluation subset, setting of remark set, and the decision of membership degree, establish evaluation system for this port coal.

3.1 *Determination of factors in evaluation*

Because there is no national standands on impact indicators for storage coal spontaneous combustion, the impact indicators is more variety and the influence is bad master of coal spontaneous combustion, so it is particularly important to develop an evaluation system for storage coal spontaneous combustion. According to the analysis of influencing factors on coal spontaneous combustion of the port, establish factor set X = {moisture, ash, volatile, sulfur}. Research found that the coal composition content record in the form of interval, in order to ensure accuracy and convenience of quantitative research results, by using averaging method to determine the content of composition and then to number different kinds of coal. Eeach component content of 18 kinds of coal as shown in Table 1.

3.2 *To determine the weight of line matrix A*

In comprehensive evaluation, taking into account the influence degree of each indicator for coal spontaneous combustion is different. Therefore it is necessary to determine the weight of each influence factor, according to literature (Jin et al. 2012, Wang 2007) and analysis of the evaluation factors can determine the weight of line matrix A = [0.2, 0.1, 0.4, 0.3].

3.3 *To calculate membership function and establish a matrix of fuzzy relation*

For spontaneous combustion tendency of storage coal at Huanghua port, X represents the evaluation set while Y represents remark set.

X = {moisture x_1, ash x_2, volatile x_3, sulfur x_4};

Y = {easy spontaneous combustion y_1, spontaneous combustion y_2, possible spontaneous combustion y_3, not spontaneous combustion y_4};

Based on the fuzziness of coal spontaneous combustion standard, it is reasonable to use the membership which is determined by membership function division classification boundary. Combined with moisture, ash, volatile, sulfur, a total of 4 internal indicators on effect of coal spontaneous

2	Shenyou 1–5800	0.77	0.86	0.66	0.29
3	Shenyou 2–5800	0.59	0.86	0.93	0.36
4	Shenyou 3–5800	0.68	0.84	0.93	0.36
5	Waigou 1–5500	0.59	0.86	0.66	0.47
6	Waigou 2–5200	0.45	0.77	0.57	0.54
7	Waigou 3–4800	0.45	0.46	0.62	0.72
8	Waigou 4–4500	0.68	0.34	0.62	0.72
9	Waigou 5–4200	0.81	0.23	0.62	0.90
10	Meager lean coal 1–5200	0.68	0.50	0.10	0.72
11	Meager lean coal 2–4800	0.68	0.34	0.10	0.72
12	Meager lean coal 3–4500	0.90	0.23	0.10	0.54
13	Meager lean coal 4–4200	0.90	0.14	0.66	0.54
14	Shenhun 1–5500	0.59	0.86	0.57	0.40
15	Shenhun 2–5200	0.45	0.77	0.57	0.47
16	Shenhun 3–4800	0.45	0.68	0.57	0.47
17	Shenhun 4–4500	0.23	0.68	0.53	0.54
18	Shenhun 5–4200	0.09	0.80	0.53	0.72

combustion tendency, according to the averaging method defines the respective membership functions on the remark set Y. Because the effect of moisture and ash to coal spontaneous combustion at this port is in reverse, its membership functions need to take the opposite values. The indicators of membership function are as follows.

$$X_1(x)=\begin{cases}0.1 & x=10\\ 1-\left[0.1+(x-10)\times\dfrac{0.9}{30-10}\right] & 10<x<30\\ 1 & x=30\end{cases}$$

$$X_2(x)=\begin{cases}0 & x=6\\ 1-(x-6)\times\dfrac{1}{50-6} & 6<x<50\\ 1 & x=50\end{cases}$$

$$X_3(x)=\begin{cases}0.1 & x=15\\ 0.1+(x-15)\times\dfrac{0.9}{35-15} & 15<x<35\\ 1 & x=35\end{cases}$$

$$X_4(x)=\begin{cases}0 & x=0\\ x\times 0.9\div 1.25 & 0<x<1.25\\ 0.9 & x=1.25\end{cases}$$

For the evaluation of 18 kinds of coal sanple consider moisture, ash, volatile and sulfur for single factor evaluation, so can use the fuzzy matrix respresents the relationship between X and Y. Then evaluation matrix R can be get.

R =

$$\begin{bmatrix}
0.63 & 0.77 & 0.59 & 0.68 & 0.59 & 0.45 & 0.45 & 0.68 & 0.81 & 0.68 & 0.68 & 0.90 & 0.90 & 0.59 & 0.45 & 0.45 & 0.23 & 0.09\\
0.99 & 0.86 & 0.86 & 0.84 & 0.86 & 0.77 & 0.46 & 0.34 & 0.23 & 0.50 & 0.34 & 0.23 & 0.14 & 0.86 & 0.77 & 0.68 & 0.68 & 0.80\\
0.93 & 0.66 & 0.93 & 0.93 & 0.66 & 0.57 & 0.62 & 0.62 & 0.62 & 0.10 & 0.10 & 0.10 & 0.66 & 0.57 & 0.57 & 0.57 & 0.53 & 0.53\\
0.29 & 0.29 & 0.36 & 0.36 & 0.47 & 0.54 & 0.72 & 0.72 & 0.90 & 0.72 & 0.72 & 0.54 & 0.54 & 0.40 & 0.47 & 0.47 & 0.54 & 0.72
\end{bmatrix}$$

According to the weight vector A, weight of moisture, ash, volatile and sulfur can be get which are 0.2, 0.1, 0.4, 0.3 respectively. thus

$n\neq 1$, A = [0.2, 0.1, 0.4, 0.3]

A is a fuzzy set of evaluation factor set X, by using fuzzy transform.

B = AR

= [0.68, 0.59, 0.68, 0.70, 0.61, 0.56, 0.60, 0.63, 0.71, 0.44, 0.43, 0.41, 0.62, 0.55, 0.54, 0.53, 0.49, 0.53]

Here, B for fuzzy sets on the comment set Y, is the comprehensive evaluation results. The order of spontaneous combustion of 18 species coal sample by B is:9# coal, 4# coal, 3# coal, 1# coal, 8# coal, 13# coal, 5# coal, 7# coal, 2# coal, 6# coal, 14# coal, 15# coal, 16# coal, 18# coal, 17# coal, 10# coal, 11# coal, 12# coal.

4 THE EVALUATION RESULTS AND DISCUSSION

According to the fuzzy relation matrix analyse the degree of coal spontaneous combustion danger of Huanghua port.

1. 1# coal which is called low ash coal spontaneous combustion tendency is quite high, but the port date shows that the storage and export capacity of such coal is less and is not stored in silo. So the size of the spontaneous combustion of such coal can not consider.
2. From the date of port, the waigou series coal are stored in the yard, so should exclude the influence of 9# coal, 8# coal, 7# coal and 6# coal.
3. For the meager lean coal, because of its low volatile content and high ash content, the spontaneous combustion tendency of this coal is lower than those of other types. By fuzzy comprehensive evaluation can also be seen that the ranking of spontaneous combustion tendency is low of this coal, so can eliminate the meager lean coal, that is, excluding 13# coal, 10# coal, 11# coal, 12# coal.

Based on the above three circumstances, the spontaneous combustion tendency of port coal is: 4# coal, 3# coal, 5# coal, 2# coal, 14# coal, 15# coal, 16# coal, 18# coal, 17# coal. this need 6 kinds of coal, so we should select larger coal spontaneous combustion tendency as experimental coal. Both 3# coal and 4# coal are shenyou series coal and they are similar to the possibility of fire, so select one of the two as the experimental coal, in this experiment 3# coal is selected. According to the above analysis, larger of spontaneous combustion tendency and selected as experimental coal are: 3# coal, 5# coal, 2# coal, 14# coal, 15# coal, 16# coal. They are shenyou 2, waigou 1, shenyou 1, shenhun 1, shenhun 2, shenhun 3.

Through the work mentioned above, storage coal spontaneous combustion evaluation system, evaluation factors and quantitative evaluation method are initially obtained. Through exploration solve the evaluation problem of coal spontaneous combustion tendency of port. In this paper, the results selected six kinds of coal can use for the later experimental study on its performance, and simulation study on its storage in silos. Provide support for the security operation of 3nd silo in Huanghua port.

5 CONCLUSION

1. This paper analyzes and builds the spontaneous combustion tendency fuzzy comprehensive evaluation system of port storage coal, completed quantitative evaluation analysis of 18 kinds of coal in Huanghua port. Results show that this evaluation system can be used to assess the capacity of coal spontaneous combustion of storage coal.
2. To select moisture, ash, volatile and sulfur 4 internal indicators which influent port storage of spontaneous combustion, can be used to evaluate the spontaneous combustion tendency of port coal storage. Geological conditions and external factors have little use to coal spontaneous combustion tendency of port, so it does not take into account in the selection factors.
3. Analysis on the assessment results found that the order of larger capacity of port storage coal and higher tendency of coal spontaneous combustion is: Shenyou 2, Waigou 1, Shenyou 1, Shenhun 1, Shenhun 2, Shenhun 3.

An LCA-based health damage evaluation method for coal mine dust

Ruipeng Tong & Yabing Zhai
Faculty of Resources and Safety Engineering, China University of Mining and Technology (Beijing), Beijing, China

Xiaodong Li
Department of Construction Management, School of Civil Engineering, Tsinghua University, Beijing, China

ABSTRACT: The health problems caused by coal mine dust are growing worse, causing mine workers serious health damages as well as economic losses. This study is based on the Life Cycle Assessment (LCA) and the coal mine unit process decomposition method, which are combined with the related environmental health and pathology. This study establishes the type indicators of coal dust health damage through collecting coal dust inventory data and it builds an assessment model that uses the health injury factors and the damage quantitative indicators. A monetization analysis is then used as the basis of a quantitative evaluation method that contains a collection of the inventory data, the type indicators of health damage, and the comprehensive quantitative values of health damage. After the application of this method within the coal mine, this study then goes on to examine society's willingness to pay for health damage caused by dust is obtained in both construction and production industries. This study shows that this method is able to quantitatively assess the extent of health damage caused by dust in the mine life cycle. Consequently, it can be used as the basis for decision making and can be provided for the use of the management of mining occupational health

1 INTRODUCTION

The effects of economic globalization mean that the health and safety damage in many workplaces is getting worse. Many developing countries in the global economy are undergoing occupational accidents and occupational diseases that arise because of rapid industrialization. Mining plays a significant role in rapid economic development. Indeed, it is one of the most important industries promoting global economic development. However, poor working conditions and serious hazardous substances in the mines can lead to a high incidence of occupational diseases, which are a serious threat to the workers' safety. China is currently the world's major coal production center. It is also one of the most affected countries by industrial disease and it suffers the world's highest incidence of occupational diseases that have been caused by the coal industry (Zou, C.Q. & Shao Q., 1999; Chen, W.H., 2006). In 2010, China's coal mines had the largest number of occupational disease cases when compared with the country's other industries. There were a total of 13968 cases of emerging diseases, accounting for 51.28% of the total number of cases (Li, F.X., 2011). Harmful toxic factors in the coal mines include mainly physical factors (such as dust, noise, heat, and hand-transmitted vibration) and toxic substances (such as CO, CO_2, SO_2, NO_2 and H_2S). However, coal dust is the most important factor among all of these harmful factors (Ai, H, 2012). For example, pneumoconiosis is an industrial disease that is caused by coal dust; it is also the major occupational disease in the coal industry accounting for about 50% of China's total cases of pneumoconiosis. The increasingly serious health damage caused by coal dust has attracted the attention of both domestic and foreign scholars and a large body of research has been conducted on this problem.

Some developed countries (such as the U.S., UK, and Australia) have had perfect researches on the health damage caused by coal dust. For example, in addition to related legislation, these studies have shown that the establishment of an occupational health management system can effectively control the incidence and mortality rate of coal mining occupational diseases. For example, Australia had set up a statutory body called *The Joint Coal Board* to control the incidence of pneumoconiosis and achieves good results. The Australian pneumoconiosis detection rate has gone from 16.0% in 1948 down to 0.5% in 2000 (Kizil, G.V. & Donoghue, A.M., 2002). Donoghue uses the *risk = probability × consequence* formula to conduct a risk assessment of the elements of coal mining that can cause damage (Donoghue, A.M., 2000). He also uses this formula to achieve a semi-quantitative method

for each risk factor, which are sorted according to the different degrees of harm. His results show that coal dust causes the most serious damage to the health of coal miners. Research has also been carried out on the relationship between the mechanism of occupational diseases and mortality, which is based on health pathology. For example, in the UK, Miller (Miller, B.G.1985) and Mcvitte (Mcvitte, J.C.1990) studied the public health and epidemiological effects of pneumoconiosis from a medical point of view and they proposed that there was a relationship between pneumoconiosis pathology and mortality. Many developed countries started to research the health damage caused by coal dust quite early in the history of the coal industry. Consequently, they established occupational health management systems and evaluation methods to a relatively sound level.

There are many domestic studies of the damage that coal dust does to health. The main themes of the current studies are listed below, including a brief description of their contents and deficiencies:

- Most analysis conforms to the status quo of the damage that coal dust causes to health, including the morbidity, and mortality of pneumoconiosis.
- Some studies find that there are problems that arise during the current domestic prevention of coal dust underground and in the control of pneumoconiosis. These studies have proposed a number of appropriate measures to improve this situation, including government and corporate management improvements, and the establishment of an occupational health management system.
- However, most of these studies conduct a qualitative discussion of the damage that coal dust does to the health of miners. Consequently, they lack a systematic theoretical and empirical analysis, and quantitative evaluation of the risk factors.
- Most of these studies have only focused on the health damage coal workers may suffer during the coal production and they lack an overall view of the full life cycle assessment. Consequently, their view of the prevention and the range of occupational injury are too narrow.

The LCA theory contains four phases, which are: definition of the purpose and scope of the study, inventory analysis, impact assessment and interpretation of the results (Ge, J. & Gong, M., 2008). Many studies in China have used the LCA theory in construction, agriculture, air conditioning manufacturing, automobile manufacturing, waste disposal and other fields. However, these studies have tended to focus on the size of the environmental impact analysis and they have rarely taken health damage into account. In view of this, this study will use LCA theory to assess the health damage caused by coal dust. Consequently, by expanding the assessment scope and the content of the study we can achieve new ideas for the quantitative evaluation of coal dust exposure.

2 THE ESTABLISHMENT OF DUST HEALTH DAMAGE EVALUATION SYSTEM IN COAL MINES

2.1 *Unit resolution and scope determination*

The decomposition research of the unit stage is very important to integrally collect the dust emissions in each stage of coal's life cycle. Combined with the actual situation of coal mines in China, the life cycle of a coal mine can be divided into: an exploration and construction stage, a production stage, an expansion stage, and a scrap processing stage (Fig 1). Although coal dust is emitted throughout the whole life of a coal mine, the quantity of pollution is unequal in each of the stages. Consequently, this study decomposes the unit of mine life cycle. To provide a basis for controlling measures, reverse tracking of the evaluation results is used to get the main components of health effects during application in a specific evaluation.

2.2 *Inventory analysis*

This study uses inventory analysis to identify and collect the inputs and outputs of the coal mine life cycle (e.g. the input of energy and material, output of dust, CO_2, and SO_2). According to the dates collected, the inventory date can be transferred into the total resource consumption and emissions of harmful substances. Without immediately connecting with the input of energy and materials in the construction and production period, coal dust is mainly caused by coal and rock crushing. Therefore, the dates of total dust emission, dust concentration in each stage, population density in each working location, space model area and the duration of the occupational disease will be collected, and the output of energy and materials will not be considered.

It should be noted that these coal mines lack relevant date records in the total emission of coal dust. The main dust production sites underground are: heading face, coal working face, shotcreting operating point, and transfer point. The dust is imported into the return air shaft through wind currents and indirect total dust emissions can be achieved as long as we get the dates of dust concentration in the air shaft and in the total return air volume.

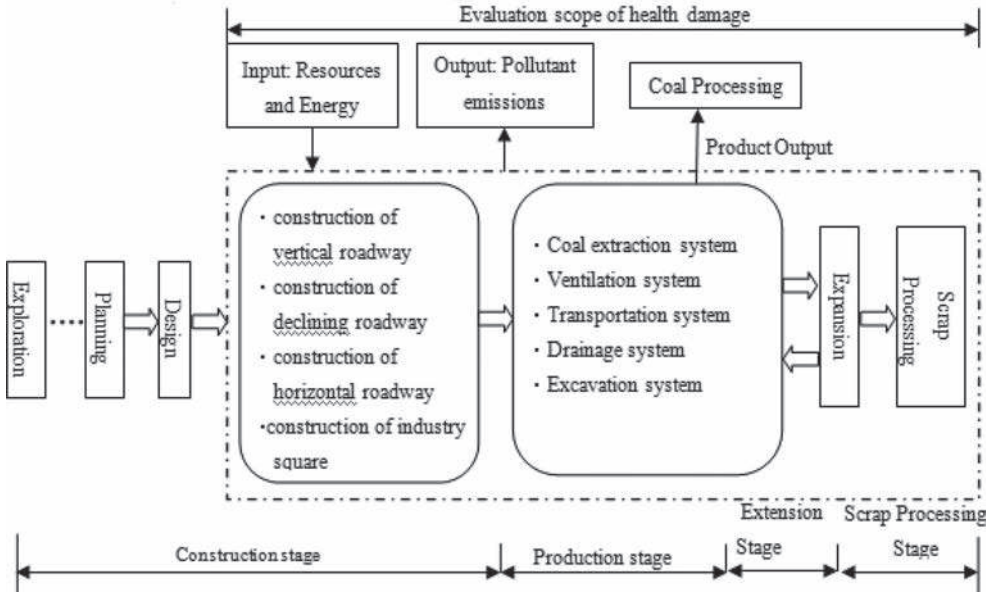

Figure 1. Evaluation of a coal mine life cycle.

2.3 *Impact assessment*

Impact evaluation has been considered to have the highest technical content, to be the most difficult, and also to be the most imperfect link of the four stages in LCA, whose main aim is classification, characteristic and quantitative. Currently, there is no clearly unified evaluation criterion between inventory dates and health damages(Gao, F., 2008). Therefore, it is important to establish a set of comprehensive and quantitative methods to transfer inventory dates into health damages.

2.3.1 *Classification*

Coal dust can lead to many health damages, such as pneumoconiosis, chronic obstructive pulmonary disease (COPD), cardiovascular disease, cerebrovascular diseases and acute respiratory infections (ARI), which all belong to diseases of the respiratory system. Therefore, the health damages caused by dust are classified into respiratory system related damage indicators.

2.3.2 *Characterization*

Characterization is able to help us choose a way to measure the impact of coal dust on the human body at various stages by quantifying the impact of dust into the same shape or by size of the same unit (Deng, N.S. & Wang, X.B., 2003) so that the severity of health damage caused by dust can be seen intuitionally. This method uses the disability adjusted life years (DALY) (WHO, 1987) to characterize dust damage to the human body because the DALY has a high degree of universality and monetization potential for various diseases (Murray, C J., 1994). Then, to convert the incidence of health damage terminal into the same quantitative indicator, impact pathway analysis (IPA) is used to determine the equivalent factor between different pollutants and quantitative indicator.

IPA can quantify the impact of substances on human health by tracing the active path of various pollutants in its life cycle. The IPA has three steps: fate analysis, effect analysis and injury analysis. Fate analysis places the health damage factors that are collected in the inventory analysis into a concentration of added value within the scope of the research space because (according to the research results of pathology) most of the quantitative analysis of relationship between the concentration of harmful substances and health damage terminals are studied in pathology. Effect analysis translates the concentration's diversification of health damage factors into the morbidity's diversification of health damage terminal and it is based on the results of epidemiological studies. Injury analysis translates the morbidity's diversification of health damage terminals into the added value of quantitative indicators (i.e. DALY). Consequently, IPA can ultimately convert coal dust emissions into the value of quantitative indicators of health damage by establishing an equivalent relationship between dust emissions and quantitative indicators.

• *Fate analysis*

The destination factor is an important parameter in fate analysis. It is a ratio between the added value of pollutant concentration in a specific environment and the annual emissions of pollutants in the same environment. The fate factor F_i is calculated as follows:

$$F_i = C_i / M_i = 1/f_0 \quad (1)$$

Where C_i is the added value of dust concentration in the air, μg·m^{-3}; M_i is the dust emissions form mine phased in a year, μg; f_o is the amount of air exchange between the inside and outside of the coal mine in a year, m^{-3}/a. Since the mine has a separate ventilation system, the annual ventilation rate of a coal mine can be regarded as the amount of air exchange.

We can then put the annual emissions of pollutants into the added value of pollutant concentration in the range of research space by using the destination factor. The conversion formula is as follows:

$$C_i = F_i \times M_i \quad (2)$$

• *Effect analysis*

Epidemiological studies often use unit risk factor (URF) to characterize the quantitative relationship between the pollutants and the health damage effects. The URF is a person's added value of number of cases of health damage terminals, which are caused by increasing the unit concentration of pollutants in their living environment. The URF can obtain the added value of number of cases of health damage terminals that is caused by increasing the unit concentration of dust in life cycle of the coal mine, which is considered as effectors. URF is calculated as follows (Hofstetter, P, 1998):

$$E_{ij} = P_d \times S \times UR_{ij} / L_t \quad (3)$$

Where E_{ij} is the effectors, case (μg·m^{-3}·a); P_d is the population density within the model space, person/m^2; S is the area of space model, m^2; UR_{ij} is the URF of health damage terminal j, caused by dust, case (μg·m^{-3}); and L_t is the average life of the population who are influenced by harmful substances, y (70 years).

The URFs of those health damage terminals have been measured and calculated as shown in Table 1(WHO, 2000):

We can obtain the added value of number of cases of health damage terminals by using the effectors and combining with the results of the fate analysis, which is caused by the emissions of harmful substances in a year. This is calculated as follows (Hofstetter, P, 1998):

$$T_{ij} = E_{ij} \times C_i \quad (4)$$

Table 1. The Unit Risk Factors of those health damage terminals.

Pollutant	Health damage terminals	UR_{ij}
Dust	Pneumoconiosis	7.7E-3
	COPD	6.0E-4
	Cardiovascular	5.3E-4
	Cerebrovascular disease	5.3E-4
	ARI	6.3E-3

Where T_{ij} is the added value of number of cases of health damage terminals, which is caused by the emissions of harmful substances in a year, case/a.

• *Injury analysis*

The DALY concept includes the years of life lost (YLL) and the years of life with disability (YLD), which is calculated as follows:

$$DALY_j = YLL_j + YLD_j \quad (5)$$

Where YLL_j is the YLL that are caused by the health damage terminal j of unit case, y/case; YLD_j is the YLD that are caused by the health damage terminal j of unit case, y/case.

Meanwhile, YLDj is calculated as follows:

$$YLD_j = L_j \times D_j \quad (6)$$

Where L_j is the duration of health damage terminal j, y/case; D_j is the disability weight of health damage terminal j.

The duration of health damage terminal can be determined according to the study of hygiene. The duration of curable diseases is formed from the onset and persists to the cure. The duration of the incurable disease is defined as the lifetime spent sick. The average of the onset of pneumoconiosis is 42 years old, so the average duration of pneumoconiosis is 20 years (Qu, S.Y. & Huang, W.L., 2012). The lifespan of cardiovascular and the cerebrovascular disease is an average of five years less than normal. The durations of related diseases are shown in Table 2:

When calculating YLD, the disability weight is used to assess the extent of damage to health of different disability statuses. A figure of 0 is considered to be completely healthy, a figure of 1 represents death; therefore, the severity of damage to human health caused by other health damage terminals is assigned form 0 to 1. The World Health Organization has identified 22 symptoms that are indicative of disability and their disability weight is used in the Global Burden of Disease Study. This present study determines the disability weight of related diseases based on the Global Burden of Disease Study (see Table 3).

Table 2. The average duration of the health damage terminals.

Health damage terminals	Duration
Pneumoconiosis	20a
COPD	10a
Cardiovascular	25a
Cerebrovascular disease	25a
ARI	14d

Table 3. The disability weight of the health damage terminals.

Health damage terminals	Disability weight (Dj)
Pneumoconiosis COPD	0.25
	0.15
Cardiovascular	0.24
Cerebrovascular disease	0.24
ARI	0.08

Finally the added value of the years of life lost (U) caused by the health damage terminal j, which is aroused by the dust emissions in the space model during a year, can be obtained via equation (4) and equation (5).

2.3.3 *An analysis of weights*

To determine which health damage type indicator gains from character analysis in terms of economic significance, the mine life cycle evaluation system uses the monetization method to determine the weights of each evaluation type. The monetization method has been internationally recognized and it has been applied in a number of systems; for example, the environmental priority strategies (EPS) system and TELLUS (Steen, B, 1996; Tellus Institute, 1992). The monetization method includes the contingent valuation method (CVM), hedonic pricing method (HPM) and willingness to pay (WTP). According to the related research at home and abroad, this study will use WTP. The WTP is the currency value that is willing to be paid to reduce the risk of death and disability. It is also used to measure and quantify the economic burden of diseases that are invisible.

After the fate analysis, effects analysis and injury analysis, an evaluation system will transform inventory analysis results into the size of health damage terminal which indicated by quantitative indicators (i.e. DALY). Weight analysis is to determine the WTP value in the unit's DALY value of life year (VLY), using the method of monetizing to determine the size of health damage terminal. To get VLY, the value of human life should be first determined and then converted into the value of a year of healthy life. The formula for calculating the life value of coal miners is as follows:

$$V_k = K \times D_k \times M_{v+m}/(S \times D) \tag{7}$$

$$K = K_1 \times K_2 \times K_3 \times K_4 \tag{8}$$

Where V_k is the economic value of the lives of miners, D_k is the average working day in their lifetime, M_v+_m is the last year's net output value of the enterprise, S is the last year's average number of employees of enterprise, D is the last year's working of the enterprise, K is the coefficient of the value of life, k_i is a person's coefficient of age, coefficient of level of education, coefficient of post and coefficient of skill levels(i is form 1–4).

Combined with the actual production of the coal mine, we can value K_1 as follows: age between 20–25, then K_1 takes the value of 0.85, age between 26–30, then K_1 takes the value of 0.95, age between 31–40, then K_1 takes the value of 1.0, age between 41–45, then K_1 takes the value of 0.95, age between 46–50, then K_1 takes the value of 0.9; $K_2 = m/22$, m is the somebody's actual education years, if he or she is an illiterate, K_2 takes the value of 0.2;we can value K_3 as following: Mining cadres takes the value of 1.1, district cadres take the value of 1.05, General Workers takes the value of 1.0; we can value K_4 as following: senior professional title takes the value of 1.15, medium grade professional title takes the value of 1.1, the primary title take the value of 1.05, General Worker takes the value of 1.0(Wang, Y.H. & Li, X.Y., 2004).

To determine the WTP value in the unit's DALY, the life value of one year must be calculated again after getting the value of the lives of miners, the equation is as follows:

$$VSLY = \frac{VSL}{\left[1-(1+r)^{-n}\right]/r} \tag{9}$$

Where $VLSY$ is the miner's life value of a year, VSL is the life value of miners, n is the life years that workers expect to remain, r is discount rate which is 4% in this paper (Friedrich, R, 2004).

The VSLY calculated above is the WTP value in the unit's DALY. Finally, the product of the health damage life of miner (U) and the WTP value in the unit's DALY is the monetary loss value of health damage caused by dust (V).

3 APPLICATION TO A COAL MINE

A coal mine in Shanxi Province that is 6.5 km long from north to south, 4.3 km wide from east to west

and covers an area of 19.59 km^2 was selected as the case. Its geological reserve is 259.62 Mt, the design reserve is 200.798Mt, and the developed reserve is 141.623Mt. The annual design production capacity of the mine is 4.0 Mt/a and the length of its service is 35 years. The engineering quantity is 32839.17 m during the mine construction, including the main and auxiliary shaft, return air shaft, shaft station and rock roadway. The central parallel exhaust system was adopted in mine production stage, selecting two BD-Ⅷ-10-No29 contra-rotating axial-flow fans with frequency control; the motor power is 2 × 280kw. In the production phase, the total air flow is 8100 m^3/min, the maximum exhaust air volume of the ventilator is 11000 m^3/min. Since the required air ventilation is less in construction than the production period, the total air volume is also less (about 4000 m^3/min). The coal dust emissions were 112 kg/a and 220 kg/a during the construction phase and in the early period of production. This increased to 140 kg/a using the optimization of coal dust reducing measures in the production period. The mine's net output is RMB680 million in 2012. During the mine's construction period there were on average 100 workers underground. During production the annual staff is about 8120, including about 400 workers on the morning shift, and about 200 workers on the afternoon and evening shift; therefore, the average working number is 300 workers.

The calculation parameters for the health loss of health damage terminal that is caused by coal dust in the construction phase are shown in Table 4.

Table 4 shows that the years of life lost caused by dust emissions in the construction phase is 2.7014 years according to the table above. The society's WTP value is RMB208, 000.

After optimizing the dust measures, the calculation parameters for the health loss of health damage terminal that is caused by the dust in the initial stage of production is shown in the Table 5 and the calculation parameters for the health loss of health damage terminal that is caused by the dust after optimizing the dust measures is shown in the table 6.

Table 5 shows that the years of life lost caused by dust emissions in the initial stage of production is 5.9003 years. The society's WTP value is RMB454, 300.

Table 6. The calculation parameters for the health loss of health damage terminal caused by the dust after optimizing the dust measures.

Table 6 shows that the YLL caused by dust emissions after optimizing the dust measures in the production phase is 3.8035 years and society's WTP value is RMB292, 900.

Table 4. The calculation parameters for the health loss of health damage terminal in the construction phase.

Total					5.9003	45.43

Table 6. The calculation parameters for the health loss of health damage terminal caused by the dust after optimizing the dust measures.

Health damage terminal Unit	F m^{-3}	M μg	E case/(μg·m^{-3}·a)	DALY y/case	U y/a	V ten thousand
Pneumoconiosis	2.3E-10	1.4E+11	2.5E-3	20.0	1.6	12.32
COPD	2.3E-10	1.4E+11	1.9E-3	16.5	1.0	7.70
Cardiovascular	2.3E-10	1.4E+11	1.7E-3	11.0	0.6	4.62
Cerebrovascular disease	2.3E-10	1.4E+11	1.7E-3	11.0	0.6	4.62
ARI	2.3E-10	1.4E+11	2.0E-2	3.0E-3	1.9E-3	1.4E-2
Total					3.8035	29.29

In the case study above, it can be seen that the years of life lived with disability caused by dust emissions in the construction phase is 2.7014 years and society's WTP value is RMB208, 000. Consequently, the economic significance is that the health damage caused by dust emissions in the production phase is equal to the loss of 2.7014 healthy years and RMB208, 000 is required to be paid to counteract this loss. Consequently, the evaluation result shows that pneumoconiosis is the most serious occupational disease during the total cycle of a coal mine, which is followed by COPD and cardiovascular disease. In addition, the dust health damage of production phase is more serious than that of the construction phase. The health damage after optimizing the dust measures is obviously lower before the improvement. The years of life lost caused by dust in the earthwork construction is 2.61, which is obtained from similar researches in architecture (Zhang, Z.H., 2008), and the value caused by toxic vapors during interior decoration is 0.29 years (Li, X.D. & Gao, Y.X., 2013). Comparing these three values, it can be seen that the coal mine dust inflicts more serious damage.

Since coal mines are generally sealed at the end of their working lives when they move into the scrap processing stage, this stage is less damaging to human health. Consequently, this study has not made a detailed evaluation of this stage.

4 CONCLUSION

This study is able to draw a number of conclusions. In contrast to the methods used in previous studies, this method has been able to apply LCA theory to study the damage that coal dust does to health. It has also been able to identify effects of coal dust throughout the range of a coal mine's full life cycle, including four stages of construction, production, expansion, and scrap processing. The evaluation methods between dust and the degree of health damage terminal are established on the basis of inventory collection.

After determining the health damage caused by dust and willingness to pay values, we find that coal miners experience more years of life lost than construction workers. According to their economic significance and model evaluation, the results indicate that coal dust poses a serious health risk and can cause considerable damage to the human body.

The dust's severity of damage in different stages of coal mine can be seen directly in the evaluation results. In addition, since the unit risk factors of health damage terminal caused by coal dust are different, the years of life lost from these health damage terminals are also different; therefore, we have been able to reach the degree of damage of health damage terminal in each stage.

The degree of health damage caused by coal dust has been significantly cut down since coal mines have taken mitigating measures to cut down on coal dust in the air. This model can be used to evaluate the merits after these measures have been taken.

Our method has used the relationship between the added value of concentration of the damage factors and the disease rate of health damage that is terminal in the epidemiological; however, there are other damage factors (such as the vibration, noise and temperature factors) that are harmful to people because they transmit energy. Consequently, our concentration value cannot be used to represent the amount of freed energy. Therefore, more research needs to be done before this method can be used to measure the health effects of other occupations.

ABSTRACT: In order to control the severe floor heave of large cross section mining roadway in No. 1 Coal Mine of China Coal Ping-shuo Group Co., ltd, the various controlling measures are simulated by numerical simulation software FLAC, such as floor bolting, pressure-relief groove and floor drilling, and the stress distribution and displacement characteristics of the roadway floor are analyzed in the condition of different measures. Additionally the combinatorial controlling measure of reinforcement method (floor bolting) and pressure relief method (pressure-relief groove) is put forward. The engineering test results show that the maximum displacement and the maximum rate of floor heave are within the controllable range. Thus the combinatorial controlling technique can effectively control the floor heave and keep the surrounding rock stable.

1 INTRODUCTION

The large cross section roadway of the fully mechanized top-coal caving is a special type of roadway affected by mining. This type of roadway is more serious than common mining roadway in the damage of surrounding rock, mainly in the concentration of floor rock horizontal stress and the change of shear stress, especially roadway passes fault, or the distance between two working faces is too small, or the interaction of multiple coal seams is obvious, and so on. (He, M.C. et a1. 2009, Yang, B.S. & Geng, X.L. 2012, Jiang, Y.D. et a1. 2004). In recent years, many scholars at home and abroad carried out the beneficial exploration on the mechanical mechanism of floor heave and the controlling measures in order to control floor heave effectively, such as reinforcement method, pressure relief method and comprehensive treatment method. But the control effect of each method varies widely due to the different engineering geological conditions. (Luo, Y.Q. et a1. 2005, Wang, W.J. & Hou, C.J. 2003, Guo, B.H. & Lu, T.K. 2008).

On the basis of former researches, this thesis tends to continue studying the stress field in floor strata of large cross section mining roadway with complicated surrounding rock, and analyzes the advantages and disadvantages of various technologies for controlling floor heave by using the numerical simulation software FLAC. Additionally the combinatorial controlling technique has been used in the auxiliary haulage roadway of No.4108 fully mechanized top-coal caving working face. The operation results show that this control technique has achieved favorable effects.

2 GEOLOGICAL CONDITION OF MINING ROADWAY

The No. 4108 fully mechanized top-coal caving working face is located in the Tai-xi mining area of No. 1 Coal Mine of China Coal Ping-shuo Group Co., ltd, it is adjacent to No. 4107 working face, its southern part is undeveloped areas, its eastern part is the chain pillar for protecting the haulage entry, its western part is Shi-xi Coal Mine. The length of No. 4108 working face is 2596 m along the strike direction, the width is 300 m along the tilt direction and the surface is hilly land. The ground elevation is from 1284 m to 1409 m, and the working face elevation is from 1050 m to 1170 m. The thickness of No.4 coal seam is from 6.05 m to 11.33 m, its dip angle is from 9° to 11°. The inclined-longwall fully mechanized top-coal caving method is adopted in the working face. The cross-section of auxiliary haulage roadway is gradient trapezoid, sectional width is 5.0 m, and sectional height is 3.4 m. During the period from May to October, 2011, the floor heave which happened in the auxiliary haulage roadway was significant.

Figure 1. Floor heave of auxiliary haulage roadway in No. 4108 working face.

The maximum of floor heave was from 900 mm to 1400 mm, as shown in Figure 1.

3 SIMULATION ANALYSIS OF FLOOR HEAVE UNDER THE ORIGINAL SUPPORTING CONDITIONS

3.1 *The geological background and numerical calculation model*

Numerical calculation model is established by using three-dimensional finite-difference software FLAC to simulate floor heave of large cross section mining roadway in No. 4108 working face. The model length is 250 m along the strike direction, its width is 200 m along the tilt direction and its vertical height is 115 m. Vertical load is applied on the upper boundary of the model according to the static weight of overlying strata. Horizontal constraints are imposed on both sides of the model. Horizontal and vertical constraints are imposed on bottom boundary of the model. Due to the study on mechanical behavior of floor failure, Mohr-Coulomb yield criterion is used to judge rock damage. (Li, Z.G. 2012, Li, X.H. et a1. 2003). The numerical modeling diagram is shown in Figure 2.

3.2 *Simulation analysis of floor heave under the original supporting conditions*

3.2.1 *The original supporting parameters*

The sectional supporting system is bolt-mesh-anchor on the roof of auxiliary haulage roadway. Each row is installed 6 bolts which are made of non-longitudinal reinforcement deformed steel bar, inter-row interval is 900 mm × 900 mm, each row is hung a steel belt, ϕ12 mm × 4600 mm. Anchor cable processed by using steel strand wires, ϕ17.8 mm × 7300 mm, is centered double row arranged, inter-row interval

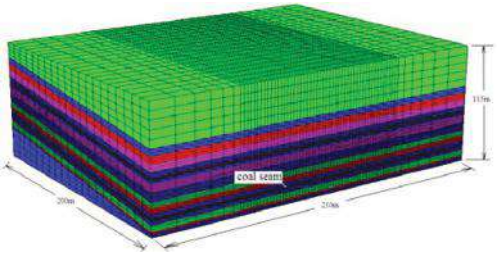

Figure 2. Numerical calculation model.

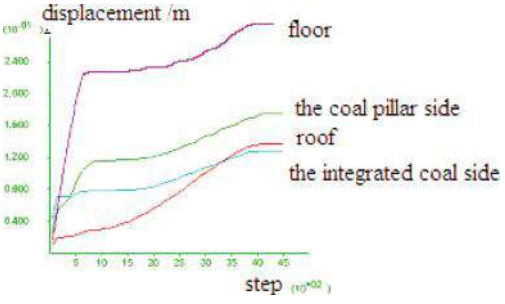

Figure 3. Displacements of surrounding rock.

is 2000 mm × 2700 mm. Each row is installed 3 bolts which are made of ordinary carbon structure round steel in both sides of the roadway, inter-row interval is 1200 mm × 900 mm.

3.2.2 *Simulation results of floor heave*

Before the simulation operation, displacement measuring points are arranged in floor, roof and both sides at different depths (located at 0 m, 1 m, 2 m, 3 m, 4 m) in order to monitor surrounding rock displacement.

First, the floor heave is larger than the amount of both side's convergence and roof sagging, as shown in Figure 3. The floor heave is generally of slope shape with the bigger heave on the coal pillar side and the smaller on the integrated coal side. Due to the large horizontal stress and the constraint role of the integrated coal beside the roadway, laminar floor strata move to free space of mining roadway, resulting in slope shape floor heave in large cross section roadway in the fully mechanized top-coal caving working face. (Gao, M.Z. & Jing, H.Q. 2012). This result is in conformity with the field measurement.

Second, the amount of floor heave at different depths is different. The deformation of floor surrounding rock located in 2 m is bigger. The displacements show a sharp growth trend to the surface of the floor. The floor strata deformation located in 5 m is smaller.

4 NUMERICAL SIMULATION ON THE VARIOUS MEASURES OF CONTROLLING FLOOR HEAVE

According to the actual geological conditions of large cross-sectional mining roadway in No.1 Coal Mine of China Coal Ping-shuo Group Co., ltd, this paper has designed three control schemes for floor heave on the basis of the original supporting parameters. The three schemes are floor bolting, pressure-relief groove and floor drilling. The research results can provide decision-making reference for field implementation.

4.1 *Floor bolting*

Numerical simulation shows that the plastic zones firstly appear in the corners of the floor. The floor heave is mainly caused by the floor strata crowding into roadway and both sides sagging. Therefore, the controlling of the floor corners is very important in large cross section mining roadway.

4.1.1 *Layout scheme*

The type of floor bolts is extension-length anchored, which are made of non-longitudinal reinforcement deformed steel bar, and the angle is 45° between the floor bolt and the horizontal plane.

4.1.2 *The effect on controlling floor heave*

The simulation results indicate that the plastic zones of surrounding rock begin to develop from the floor corners where the scope of plastic zone is biggest. The floor bolts which have been installed immediately after the exposure of surrounding rock improve the floor strata strength, change the regional stress distribution, and reduce the bottom horizontal stress. Therefore the floor bolts play a positive role in resisting floor heave.

4.2 *Pressure-relief groove*

4.2.1 *Layout scheme*

Pressure-relief groove is excavated on the floor near the side of coal pillar. (Sun, J. & Wang, L.G. 2011). Considering the convenience for transportation and pedestrian safety, the groove width is 300 mm. The Figure 4 shows stress distribution and displacement characteristics of floor strata at different depths of the grooves, such as 0.2 m, 0.3 m, 0.5 m, 0.7 m, 1.0 m, 1.3 m, 1.5 m.

4.2.2 *The effect on controlling floor heave*

First, the growing trend of floor heave has been effectively controlled by cutting pressure-relief groove. The floor strata move to the groove free space so as to reduce the amount of floor heave.

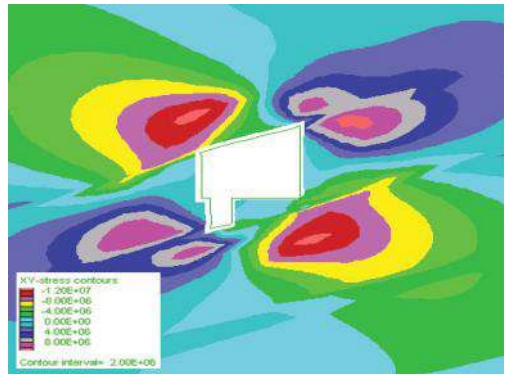

Figure 4. Shear stress distribution of the pressure-relief groove.

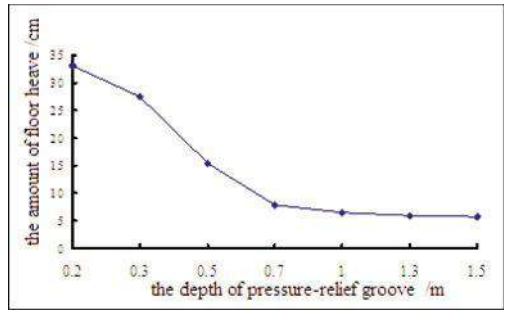

Figure 5. Displacement curve of floor strata after cutting pressure-relief groove at different depths.

If the groove is longer and wider, this kind of phenomenon could be more obvious.

Second, the scope of plastic zone in floor corners is influenced by cutting pressure-relief groove at different depths. The pressure-relief groove can transfer high stress to the deeper strata. The deformation energy can be released. Additionally the groove cutting and roadway excavation should be constructed simultaneously in order to make the cutting of pressure-relief groove become a part of roadway excavation.

Third, the displacement curve of floor strata after cutting pressure-relief groove at different depths is shown in Figure 5. When the groove depth is less than 0.5 m, the amount of floor heave is still large and the controlling effect is not obvious. When the groove depth is 0.7 m ~1.0 m, the amount of floor heave has reduced effectively, the inflexion point is found at the curve. Based on site conditions and the actual operation, the depth of pressure-relief groove is determined as 0.7 m ~1.0 m.

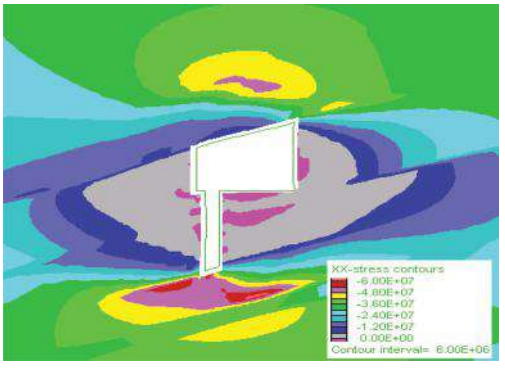

Figure 6. Horizontal stress distribution of the floor drilling.

4.3 *Floor drilling*

4.3.1 *Layout scheme*

Based on site conditions and the convenience of traffic, boreholes are drilled in the floor strata near the side of coal pillar. The borehole's diameter is 42 mm. (Wang, W.J. & Feng, T. 2005). Figure 6 shows the stress field and displacement distribution of floor boreholes at different depths, such as 1.0 m, 1.5 m, 2.0 m, 2.5 m, 3.0 m, 3.5 m.

4.3.2 *The effect on controlling floor heave*

First, the numerical simulation results show that the floor boreholes can transfer high stress to the deeper strata, the shallow strata stress can be reduced significantly. This result has ensured the stability of the large cross section mining roadway. But the convergence of roadway sides affected by floor drilling is not obvious.

Second, the stress redistribution around the boreholes is an important factor which results in the generation of the loose zone and plastic zone. Under the action of high stress, deep strata have the trend to move towards to the free surface. Therefore, the amount of floor heave in the deep strata is decreased.

Third, compared with other controlling measures, the initial moving point of the floor strata is deeper by adopting the floor boreholes, the boreholes are drilled much deeper than pressure-relief grooves. So the construction period is longer and the actual operation is more complicated.

4.4 *Comparative analysis on the different measures of controlling floor heave*

Through the comparative analysis on the above control schemes of floor heave, the key parts of controlling floor heave are the floor corners and floor rock affected by mining. The first program is reinforcement method, floor bolting, changing the stress distribution, reducing the horizontal stress and strengthening the overall strength of surrounding rock. The second program is pressure relief method, pressure-relief groove, providing the free space for high horizontal stress transfer. The third program is pressure relief method, floor drilling, although floor strata stress can also be significantly reduced, but the construction is too complicated. Based on the practical conditions of large cross-sectional mining roadway, the combinatorial controlling technique of reinforcement method (floor bolting) and pressure relief method (pressure-relief groove) is put forward. This combinatorial technique could be able to give full play to their respective advantages.

5 ENGINEERING PRACTICE

5.1 *Floor bolting reinforcement supporting at floor corners*

According to the results of numerical simulation and in-situ operation conditions of No.1 Coal Mine of China Coal Ping-shuo Group Co., ltd, the whole train of thought is identified as: on the basis of the original supporting parameters in large cross section mining roadway, the control technology of floor bolting reinforcement supporting at floor corners is adopted. The floor bolts are extensible anchoring, made of non-longitudinal reinforcement deformed steel bar, the bolt diameter is 22 mm, its length is 2400 mm, and the angle between the floor bolt and the horizontal plane is 45°. The supporting parameters are shown in Figure 7. Field application shows that floor bolting can limit the expansion of plastic zone, prevent floor heave, and improve the overall supporting effect of large cross section roadway.

5.2 *Pressure-relief groove cut in floor*

According to the results of numerical simulation, the parameters of pressure-relief groove are identified, its width is 300 mm, and its depth is 800 mm. Considering the convenience for transportation and pedestrian safety, pressure-relief groove excavated in floor corners (the junction between coal pillar and floor) should be filled up with flexible materials such as sawdust, fine sand and so on. The strength of the filling material should not be greater than floor rock. This technical innovation not only realizes horizontal stress transferring to the groove, but also prevents the floor strata from expanding up under the influence of water. The layout parameters of pressure-relief groove and the actual operation are shown in Figure 8.

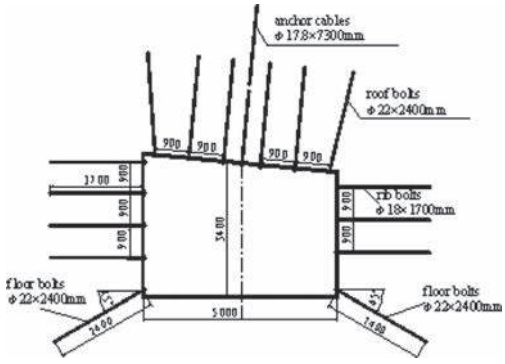

Figure 7. Schematic diagram of floor bolting reinforcement supporting.

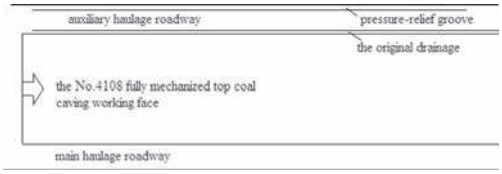

Figure 8. Pressure-relief groove layout parameters.

5.3 *Controlling effects on floor heave*

Trough the above technical measures, the industrial application have been carried out in the auxiliary haulage roadway of No.4108 working face. The technicians have monitored the amount of floor heave at the same time. The monitoring results show that the maximum displacement of floor heave is 232 mm and the maximum rate is 19.3 mm/d. The maximum displacement and rate are within the controllable range, as shown in Figure 9. Compared with the former supporting measures, the gradually decreased tendency of floor heave at the auxiliary haulage roadway has presented through the combinatorial controlling technique. Thus, the combinatorial controlling technique can effectively control the floor heave and keep the surrounding rock stable. The actual operation is shown in Figure 10. In practice, the technique has ensured that the pedestrian and material transportation are unimpeded and has achieved good technical and economic benefits.

6 CONCLUSIONS

Firstly, engineering practice shows that the combinatorial controlling technique of reinforcement method (floor bolting) and pressure relief method (pressure-relief groove) has achieved remarkable

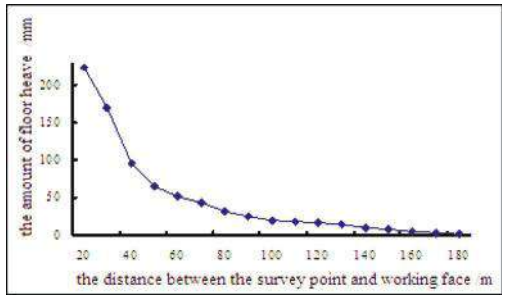

Figure 9. Displacement curve of floor heave by adopting the combinatorial controlling technique.

Figure 10. The actual operation by using the combinatorial controlling technique.

effects. This technique can effectively control floor heave within the allowed range and keep the surrounding rock stable.

Secondly, this technical innovation of pressure-relief groove not only realizes horizontal stress transferring to the groove, but also prevents the floor strata from expanding up under the influence of water. The pressure-relief groove cutting and roadway excavation should be constructed simultaneously. The cutting of pressure-relief groove becomes a part of roadway excavation. Considering the convenience for transportation and pedestrian safety in the large cross section mining roadway, pressure-relief groove is excavated at the floor corner (the junction between coal pillar and floor), which should be filled up with flexible materials such as sawdust, fine sand and so on.

Thirdly, the numerical simulation method can reveal the stress and deformation characteristics of floor surrounding rock with various kinds of controlling measures, this is conducive to optimizing the design scheme, reducing the testing time and improving economic and social benefits.

ABSTRACT: Based on thermal analysis kinetics and combined the thermo-gravimetric experiments of two coal samples: 065–2 working face of Gu-Shan Mine and silk carbon layer with STA449C TGA Test System, calculated the kinetic parameters of two coal samples and coal added inhibitor kind, and quantitatively analyzed the activation energy in the reaction stage. The results show that the inhibitor rate is defined as a percentage of the activation energy difference between the original coal samples and adding inhibitor ones compared with the original coal samples activation energy in oxygen increasing stage and the best inhibitor ratio parameters of FR-1 is 1:2 in Gu-Shan Mine. Validated inhibition effect of FR-1 through field application, which effectively prevented spontaneous combustion of 065–2 working face and guaranteed to produce safely and go over the fire zone successfully. The results have theoretical and practical significance to select inhibitors of spontaneous ignition of coal and find the optimum ratio parameters.

1 INTRODUCTION

The coal spontaneous combustion in coal mine shaft is one of current coal production significant natural disasters (Li 1998). Mining the spontaneous combustion tendentious coal bed mine occupies the similar mine 47% in our allocation and key coal mine, which has more than spontaneous combustion 300 times every year. In addition another spontaneous combustion tendentious coal bed, the number will reach 600 times every year, causing the giant person casualties and the economic loss and threatening the coal mine safety seriously, affecting the coal mine economic efficiency (Luo et al. 2003, Wang 2005).

The inhibitor is a kind of effective measures to prevent coal spontaneous combustion (Jiao et al., 2012). At present, inorganic salt solution and silicone gel used inhibitors are used in China (Wang et al. 1990, Zhang 1999), inhibiting major mechanisms of which are liquid membrane preventing oxygen and reducing temperature theory. Its main drawback is the high cost of fire prevention, unguaranteed inhibition effect, few sources of drugs and difficult purchase. In recent years, lots of new type inhibitor have been developed, such as DDS series composite inhibitor, polymer emulsion inhibitor, water soluble inhibitor and powder thermal protection agent and so on (Zhang et al. 1995, Dong 1997, Yang et al. 1999). So, it is extremely important to quantitatively determinate the inhibition effects and rates of coal inhibitors. However, it has not been a good way to identify resistant effect. In China, inhibition rate has being been adopted that a percentage of the CO difference between the original coal sample and adding inhibitor one compared with CO of the original coal sample at 100°C. However, the short comings of this method (Lu et al. 2005) are that the measuring apparatus is relatively complicated and test time is too long. This article discusses a new method of thermal analysis, which is convenient for practical application for simple measuring device and reliable test result.

2 EXPERIMENTAL APPARATUS AND CONDITIONS

Thermo-gravimetric analysis of this experiment is carried out on STA449C TGA Test System (Fig. 1). Experiment conditions: ①Sample size: 200 item;

Figure 1. STA449C TGA Test System.

②Heating rate: 5°C/min; ③Initial temperature: 25°C, end temperature: 800°C, ④Experimental atmosphere gas: Nitrogen and Oxygen (4:1); ⑤The initial sample quality: 15 mg~20 mg.

3 COAL OXIDATION REACTION KINETICS MODEL

3.1 *Activation energy*

Activation energy is the minimum energy required to start a chemical reaction (Liu et al. 1999, Deng 2006), which can be thought of as an energy "hill" or barrier that must be crossed before reactants can proceed to form products.

3.2 *Kinetic model of coal combustion*

Reaction kinetics of coal combustion in oxygen-enriched environment is investigated by non-isothermal method in this work. The reaction kinetic equation of coal combustion can be expressed as (Liu et al. 2005, Li 2007, Shan et al. 2005, QI et al. 2010):

$$\frac{d\alpha}{dt} = Ae^{-\frac{E}{RT}} f(\alpha) \tag{1}$$

$$\alpha = \frac{m_0 - m_1}{m_0 - m_\infty} \times 100\% \tag{2}$$

$$f(\alpha) = (1 - \alpha)^n \tag{3}$$

Where A is pre-exponential factor, min^{-1}; E, activation energy, kJ/mol; R, general gas constant, 8.314×10^{-3} kJ·mol^{-1}·K^{-1}; α mass conversion fraction; n, reaction order. $f(a)$ is the reaction mechanism function; m_0, mass of the sample at the beginning of reaction; $m_\perp$, mass of the sample at the end of reaction; m_t, mass of the sample at time t.

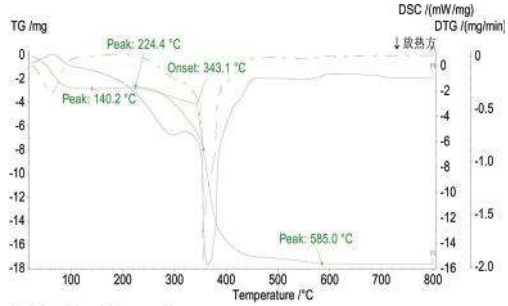
The parameters E and A of the coal samples were obtained from the kinetic analysis of TG data. The Coats-Redfern method has a great advantage of simplicity among the kinetic approaches and is extensively acknowledged. The reaction kinetic equation can be deduced as:

$$\ln[\frac{g(a)}{T^2}] = \ln\{\frac{AR}{\beta E}[1 - \frac{2RT}{E}]\} - \frac{E}{RT} \tag{4}$$

Since the E value is large, 2RT/E can be approximately equal to zero. According to the chemical reaction order, formula left on reciprocal temperature.

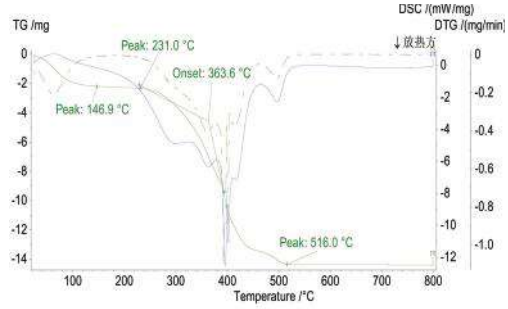
$1/T$ for the photo shows a straight line. As a result, E can be calculated from the slope, and A can be calculated from the intercept.

4 EXPERIMENTAL RESULTS AND ANALYSIS



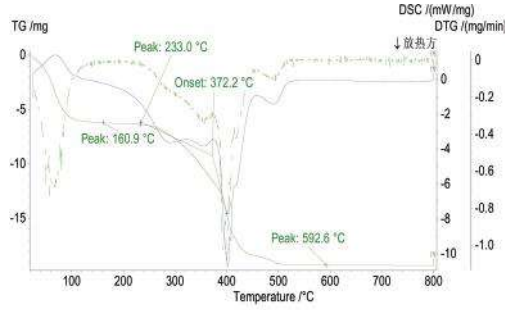
In order to find the optimal ratio of FR-1, coal samples (coal sample of 065–2 mine face and silk carbon layer) were immersed respectively in the different proportions inhibitor(the volume ratio of Foam Retardant-1 and water is 1:1, 1:1.5, 1:2, 1:2.5, 1:3) for one day. Then the coal samples were dried two days in desiccators. The experiments were carried out using Simultaneous Thermal Analysis STA449C produced by Nietzsche of German.

4.1 *Thermo-gravimetric characteristics analysis*



TG is based on continuous recording of mass changes of a sample of material, as a function of a combination of temperature with time, and additionally of pressure and gas composition. The TG curves reflect weight changes of coal sample in the process of coal oxidation caused by coal oxygen complex and various gases desorption and escape.

Several combustion parameters such as temperature of water the best evaporation (T_1), the beginning pyrolysis temperature (T_2), ignition temperature (T_3) and burnout temperature (T_4) were achieved by analyzing the TG and DTG curves.



As shown in Fig. 2, whether additional inhibitor or not, the general trend of coal samples TG curves are divided into five stages: Water evaporation to weight lessness (T_0~T_1), oxygen increase to heavy (T_1~T_2), coal thermal decomposition (T_2~T_3), the combustion (T_3~T4) and the burnout ($T > T_4$); The weight of the coal sample have been basically reduced because he physical oxygen role are suppressed after adding the inhibitor to coal samples. And the quality of the coal samples reduced slowly

	1:2.5	138.0	247.0	365.7	531.9

for the weak oxygen-absorbing effect in the oxidation weight gain stage (T_1~T_3).

As observed from Table 1, the ignition temperature T_3 of coal samples increased after adding inhibitor; when the inhibitor ratio was 1:2, it reached the maximum value on the same coal sample.

4.2 *Kinetic Parameters*

According to Esq. 4, if a correct model is select for the reaction, the plot of $\ln[g(a)/T^2]$ versus $1/T$ will be linear with high-correlation.

By comparing correlation coefficient r in Table 2, it found that the correlation coefficients r of the coal samples in different reaction stages are bigger using first-order reactions than others, which

indicates the stages meet first-order reactions in the reaction model; adding the inhibitor into coal samples, $T_0 - T_1$ and $T_2 - T_3$ stage basically meet first-order reactions in the reaction model; $T_1 - T_2$ stage belongs to three-dimensional reaction in diffusion mechanism model and $T_1 - T_3$ stage belongs to the one-dimensional model of diffusion mechanism reaction.

Kinetic parameters of various coal samples in different inhibitor ratios with the different reaction models of combustion reaction are calculated respectively from experimental data: apparent activation energy (E) and apparent frequency factor (A) of the reactions.

Calculating results are listed in Table 3.

4.3 *Optimal ratio of FR-1*

As shown in Fig. 3 and Fig. 4, the activation energy of 8 coal sample is lower than the one of 3 coal sample, indicating that the coal spontaneous combustion tendency of the carbon layer with wire is larger than the ordinary one, more likely to catch fire.

But the coal ignition activation energy of coal samples added inhibitor become smaller than coal samples without the inhibitor.

On the one hand, T_1-T_3 stage of coal samples with the inhibitor belong to one-dimensional reaction of the reaction diffusion mechanism model rather than first-order reactions in the reaction model. On the other hand, because the water content of FR-1 Foam inhibitor reaches as high as 90%, Liquid films are formed, what cut off oxygen and reduce the temperature before 100°C. The coal water evaporation is decreasing; to a certain point, resistance change into promoting the coal spontaneous combustion with the temperature increasing.

The activation energy of ignition and ignition temperatures at different inhibitors ratios are shown in Fig. 5. As inhibitors ratio decreases, the ignition activation energy first increase, then reduce. When the ratio of FR-1 is 1:2, all ignition activation energy reaches maximum value, which mean best resistance ratio.

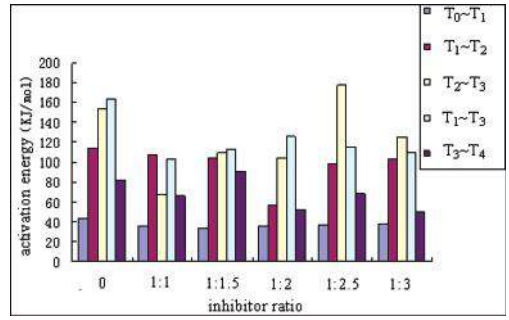

Figure 3. Activation energy of each stage of No.3 sample at different inhibitor ratios.

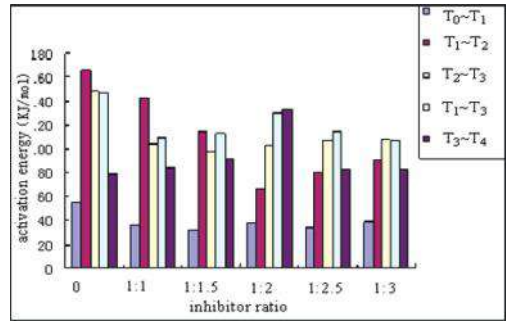

Figure 4. Activation energy of each stage of No.8 sample at different inhibitor ratios.

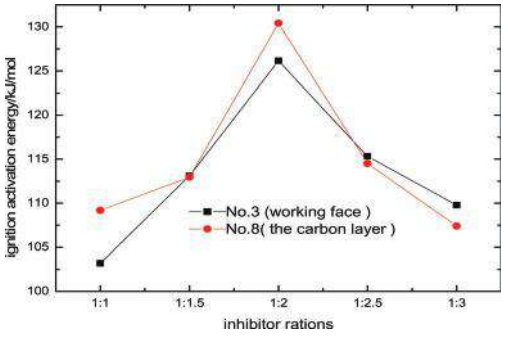

Figure 5. The activation energy of ignition at different inhibitors Ratios.

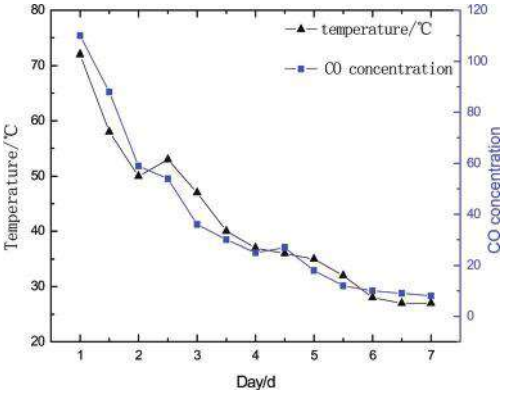

Figure 6. Variation of temperature and CO concentration after pouring FR-1 retardant.

4.4 *The inhibitor rate*

The percentage of activation energy differences of oxygen stage ($T_1 - T_3$) between the original coal samples and adding inhibitor ones compared with the activation energy of the original coal samples is called inhibitor rate. The inhibitor rate value can be taken from Eq.5:

$$E = \frac{B - A}{A} \times 100\% \tag{5}$$

Where E is resistance rate, A is activation energy in oxygen stage ($T_1 - T_3$) of the original coal samples and B is activation energy in oxygen stage ($T_1 - T_3$) of adding inhibitor coal samples in the same test condition.

Thus, resistance rate of No.3 and No.8 samples in the inhibitor ratio 1:1, 1:1.5, 1:2 1:2.5, 1:3 are as follows: 5.86%, 8.18%, 50.63%, 13.52%, 9.57%; 13.64%, 30.54%, 59.96%, 51.41%, 45.6%.

5 APPLICATION OF FR-1

In order to produce safely and go over the fire zone successfully, mixed the FR-1 polymer liquid foam inhibitor and water according to the proportion of 1:2. Use special foam device to create the inhibitor foam. And then put out fire by means of pour this material into the hidden danger areas of spontaneous combustion through compressed air pipe or inert gas injection pipe. PU's foam equipment consists of special pump, solvent tank, foam maker and air line and so on.

Take B4–2 drilling of fire zone in Gu-Xin small coal mine as an illustration. CO concentration was 0.012%, O_2 concentration was 4.3%, and the gas temperature was 72°C. Inject the foam inhibitor 100 Kg to the beyond-standards danger zone by B4–2 drilling. The volume of the foam filling was 45.5 m^3 according to foam multiple of 500. Then, validate the effect through adjacent boreholes. The results of test are shown in Fig. 6.

The results show that CO concentration and gas temperature decrease with injection time increased. The two indications reduced to the fire zone extinction standard of coal mine safety regulation within 4 to 5 days. That is to say air temperature of detection zone decreased to below 30°C, the oxygen concentration is reduced to below 5%, the concentration of carbon monoxide reduced to below 0.001%. Injecting FR-1 polymer liquid foam inhibitor played a significant role in eliminating the high temperature point and preventing coal mine fire.

6 CONCLUSION

Based on the TG/DTG profiles, the kinetics parameters such as activation energy (E) and frequency factor (A) were obtained by Coats-Redfern method. The following conclusions can be drawn:

1. The best inhibitor ratio of FR-1 in Gu-Shan Mine is 1:2.
2. The inhibitor rate is defined as the percentage of activation energy in oxygen increasing stage ($T_1 - T_3$) between the original coal samples and adding inhibitor ones compared with the original coal samples activation energy. It had theoretical and practical significance to select inhibitors of spontaneous ignition of coal and find the optimum ratio parameters.

ABSTRACT: According to Pang Zhuang mine 7431 fully mechanized caving face situation, along the goaf orientation layout of 4 measuring points and determination of goaf gas composition, using three order spline interpolation methods, according to O_2, CO concentration determined "three zones" scope and the residual coal in the oxidation zone time. Finally, According to the "three zones" determine the implementation technology of fire prevention and control techniques, effectively prevent the spontaneous combustion of residual coal in goaf and ensure the safety of coal mining face.

1 INTRODUCTION

Goaf is one of major hazard source in coal major disasters; many accidents and mine are almost in goaf with some factors. With the development of mining technology, spontaneous combustion risk of the residual coal in the goaf will become more and more serious. In recent years, with the continuous development of high yield and high efficiency new technology, increasing mining intensity range, mining empty area expands unceasingly, especially in fully mechanized top coal caving goaf spontaneous combustion of coal seam, left a large number of coal, the coal spontaneous combustion fire prevention in goaf of fully mechanized top coal caving mining becomes the key factor of success.

Analysis of spontaneous combustion of Residual coal in goaf, Determination of the actual condition of "three zones" distribution of goaf, spontaneous combustion danger area and morphology For determine the ventilation mode, the optimization of ventilation parameters and Determining safe speed of coal mining face, Ensure that the goaf float coal spontaneous combustion danger does not appear have very important realistic meaning (Yang et al. 2000, Shi & Qin 2012).

2 GENERAL SITUATION OF WORKING FACE

Pang Zhuang mine 7431 working face of coal seam belongs to coal 7# and the coal seam thickness change range is 2 ~ 5 m, the average thickness of 3.5 m. The gateroad of working face strike length is 1200.7 m and Slope length is about 120 m. Working face ventilation by using "U" type ventilation. According to the mine gas classification, Pang Zhuang mine belongs to the high gas mine, coal dust has explosion hazards, Coal seams have spontaneous combustion tendency, and the spontaneous combustion grade is I or II that is easy to spontaneous combustion or spontaneous. Coal spontaneous combustion period is generally 5 to 12 months, the shortest was 1 ~ 3 months.

3 "THREE ZONES" DIVISION OF GOAF

With the working face advance, because of the mine pressure, when the coal caving zone from loose (cooling zone) gradually into the roof separation zone, Falling rocks began to pressure, and gradually the compaction, the porosity decreases, air resistance increases, the air leakage intensity is prone to state of spontaneous combustion of residual coal, At this time Significant increase in temperature, decrease of oxygen concentration, carbon monoxide concentration increased (Oxidation zone) (Li et al. 2011).

With the working face further advance, when the falling rock gradually Enter the compaction zone, because the air leakage is reduced, the oxygen concentration is difficult to sustain the spontaneous combustion of residual coal, originally residual coal in spontaneous combustion state but

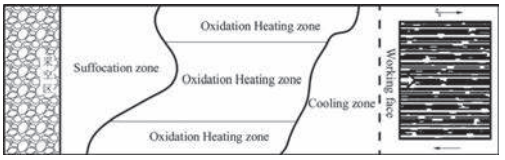

Figure 1. The goaf spontaneous combustion danger zone static distribution diagram.

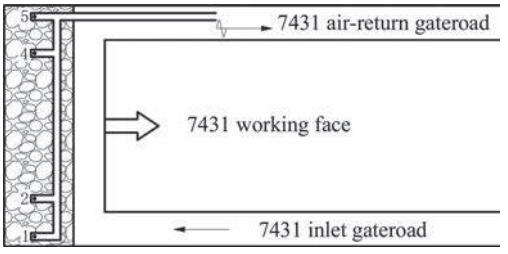

Figure 2. The temperature measuring and sampling test point arrangement schematic diagram of 7431 working face.

also because of hypoxia and asphyxia. Now the temperature began to decline slowly, carbon monoxide concentration gradually slowing down (Suffocation zone) (Yang & Cheng 2011).

In addition, because of the goaf Fresh air lane within the fresh air leakage, so the oxygen concentration decreased slowly while the Return air lane within the Air leak congruence, Airflow by oxidation and resulting gas influx, oxygen concentration decreased rapidly and Carbon monoxide concentration is relatively high. "three zones" distribution diagram is shown in Figure 1.

4 GOAF "THREE ZONES" OF MEASUREMENT AND ANALYSIS

4.1 *The establishment of beam tubes sampling analysis system*

Pang Zhuang mine 7431 working face Slope length is about 120 m, In the Supply and return air side respectively, the arrangement of 2 measuring points, Each measuring point embedding a beam tube (with the working face advancing step by step, 4 points respectively into the cooling zone, spontaneous combustion zone and suffocation zone), in the pumping station with explosion-proof pump pumping gas, sampling gas composition analysis by China University of Mining and Technology spontaneous combustion simulation dedicated chromatography laboratory. Sampling test point arrangement diagram is shown in Figure 2.

4.2 *Determine the goaf width of "three zones"*

Based on the comprehensive analysis of O_2 and CO concentrations of 4 Measuring point along the goaf strike length, concentration changes of O_2 and CO of The air intake side of 1 and 2 point and The return air side of 4 and 5 points is shown in Figure 3 and Figure 4.

First point from Figure 3, Figure 4 shows oxygen concentration of the inlet side was significantly higher than the return air side, and CO concentration of the air inlet side of was significantly lower than the return air side, This is mainly because the air inlet side leakage is large, there have been fresh

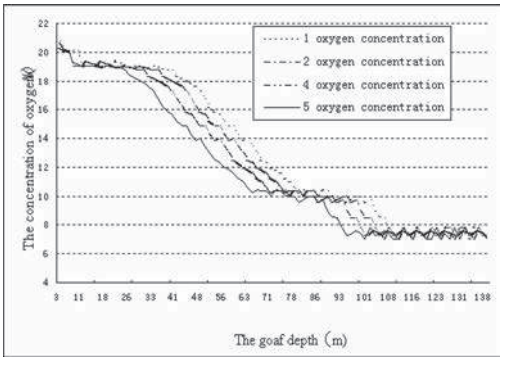

Figure 3. The O_2 concentration along the goaf depth diagram.

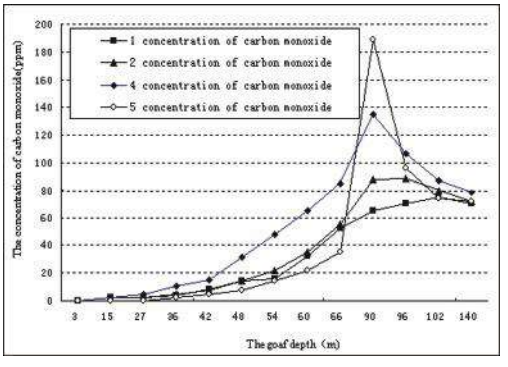

Figure 4. The CO concentration along the goaf depth diagram.

air supplement to dilute the concentration of CO, and take some of the heat, And higher CO concentration of the return air side is due to the return air side oxidation more intense consume large amounts of oxygen, this is caused by oxidation of goaf coal Produces CO With the continuous accumulation of air leakage to the return air lane.

Table 1. Division of distribution table of goaf "three zones" According to the O_2/CO concentration.

Measuring point	Cooling zone (m)	Spontaneous combustion zone (m)	Suffocation zone (m)
1(O_2/CO)	30/28	106/102	106/102
2(O_2/CO)	28/27	101/98	105/98
4(O_2/CO)	19/15	96/94	96/94
5(O_2/CO)	13/14	90/88	90/88

Table 2. Working face goaf "three zones" Range table.

Measuring point Position	Cooling zone (m)	Spontaneous combustion zone (m)	Suffocation zone (m)
Air intake side	0~27	27~106	106
Return air side	0~13	13~96	96

Second point with the working face advancing O_2 concentration of goaf decreased, and the concentration of CO increased gradually. Comprehensive analysis of goaf oxygen, carbon monoxide, the parameters of coal oxidation and spontaneous combustion "three zone" is classified by oxygen concentration: (O_2) > 19% is cooling zone, 15%< (O_2) < 19% is spontaneous combustion zone, (O_2) <15% is Suffocation zone. On the basis of changes in concentration of oxygen and CO, By using MIN-MAX optimization theory (Chen & Wang 2009), According to the concentration of oxygen and reference CO concentration classified: The minimum value of the two in cooling zone, The maximum value of the two in spontaneous combustion zone and the range of "three zones" in goaf, as shown in Table 1, shown in Table 2.

5 GOAF FIRE PREVENTION MEASURES

5.1 *Fire prevention mechanism of three-phase foam*

China University of Mining and Technology developed a fire new technology of three-phase foam for preventing spontaneous combustion of coal (Zhang et al. 2006). Three-phase foam fire extinguishing technology Take materials, gas liquid solid three phase fire extinguishing performance As a whole, Make full use of coverage of fly ash or yellow mud and Asphyxiant of nitrogen and water cooling for fire prevention and control(Smith & Lazzara 1998). Field application shows: treatment and prevention of three-phase foam fire extinguishing technology of spontaneous combustion, large fire of coal in goaf and ignition location unknown area, Fully mechanized caving face high and tunnel High fire, inclined downward goaf of fully mechanized caving face spontaneous combustion of coal, the result is quite remarkable (Li 2006). The fire extinguishing mechanism:

First point seal the coal, isolation of oxygen, plugging leakage channel and fracture of coal body.

Second point heat absorption and cooling, reduces coal body and the surrounding environment temperature.

Third point reduces the goaf oxygen concentration, inhibiting oxidation of coal, coal spontaneous combustion of asphyxia.

Fourth point Wetting coal, increase the moisture of coal.

And so on inhibiting production of coal free radicals, blocking the chain reaction of free radicals in the existing (Kang & Chen 2010).

5.2 *Process perfusion of three-phase foam*

First point three-phase foam preparation

For the appropriate concentration of slurry, the first station ahead of supply 10 min water in the grouting, grouting pipe flushing; then began to injection the mud; when the slurry injection foaming agent to the location, Start the screw pump, the foaming agent according to the quantitative ratio into the grouting pipe; When the mixed liquid slurry and foaming agent reaches foaming device, then open the gas valve to supply, three-phase foam formed at this time into the need to fire prevention area, three-phase foam filling process is shown in Figure 5.

Second point perfusion of three-phase foam

In the working face of the air inlet side along the goaf embedded 5–10 m length of the thick wall steel pipe as the foam injection pipeline, the movement mainly uses the face hydraulic support for traction, foam injection tube moving with the working face advancing. Foam injection port position should be inserted into the working face goaf spontaneous combustion zone, i.e. away from the work face scraper-trough conveyer 5–10 m range.

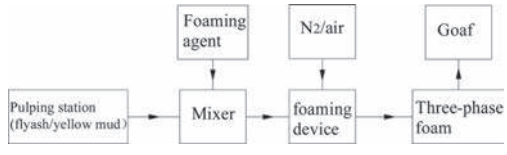

Figure 5. Three-phase foam perfusion flow chart.

6 CONCLUSIONS

First point with the working face advancing, the oxygen concentration of goaf each measuring point decreases gradually, spontaneous combustion "three zones" of goaf has been moving forward.

Second point in 7431 working face goaf oxygen concentration and CO concentration actual measurement, using the MIN-MAX optimization theory to determine the "three zones" width of working face goaf, from the working face mining deep space 0 ~ 27 m for the scattered tropical, 27 ~ 106 m is oxidized zone, More than 106 m is suffocative zone.

Third point according to the actual situation of the "three zones" of working face goaf put forward the corresponding Fire prevention measures of three-phase foam. Three-phase foam Fire prevention, not only make the goaf oxygen concentration greatly reduced, but also quickly reduce the residual coal temperature, can effectively prevent the spontaneous combustion of coal.

And so on During the whole goaf of temperature measuring and sampling observation (A range of about 140 m), the data analysis results measured by each: Spontaneous oxidation of Residual coal in goaf is always in the latent period, self-heating period (Generally self-heating Early period) two stages, no occurrence of spontaneous combustion of coal in goaf. But in the Fresh air lane side away from the work face about 90 ~ 100 m and return air lane side about 85 ~ 96 m "spontaneous combustion zone" range. CO appeared wave crest. These shows in these areas (especially in the Fresh air lane side) are high temperature heat source and the local coal spontaneous combustion is more intense.

Active pressure determination under the condition of rapid determination of gas pressure

Shu Yang, Genyin Cheng & Liming Qi
North China Institute of Science and Technology, Yanjiao, Beijing, China

ABSTRACT: The gas pressure in coal seam is one of the important basic parameters. Accurate and quick determination of the gas pressure in the coal seam has not only great significance for the determination of gas content in coal seam, for the control of mine gas emission, for gas drainage, and for the prevention of coal and gas outburst, but also has economic and social benefits for the safe production of coal mine. There are direct method and indirect method on the determination of gas pressure in the coal seam. Direct determination method includes active manometry and passive manometriy. This paper, on the premise of active manometriy, explores a method to rapidly determine gas pressure.

Keywords: gas pressure, manometric method, grouting hole

The prevention of gas accidents is the key of the key in the coal mine security work. To effectively prevent and control gas accidents, we must first accurately measure the gas pressure. In general, two broad headings of methods are proposed, —direct determination method and indirect determination method. The pattern of direct determination method includes active manometric method and passive manometric method. Active manometry is to measure the pressure by aerating compensation gas into coal seam through the drill hole so as to balance the gas pressure, and therefore to determine the gas pressure. The compensation gas can be high-pressured Nitrogen N_2 high-pressured carbon dioxide CO_2 or other inert gas. The barometric pressure of compensation gas should be slightly higher than the expected gas pressure in coal seam. The passive manometry is to measure the gas pressure through the natural infiltration of the gas into coal seam after the drill hole sealed, to achieve the balance of gas pressure.

According to an incomplete statistics, the successful rate of drilling manometry is no higher than 70%, and the scrap rate of some manometry hole is as high as 50%. Besides, it often takes the passive manometry at least about a month or several months to complete one measure cycle—(Xun Bingxing, et. al, 2010) This manometry, with relatively long measure cycle, low success rate and high error risks, wastes a lot of financial resources, delays the production cycle, leads to wrong technical judgment, and has high potentiality of accidents. Therefore, this paper expects to explore a determination method or approach, under the premise of active manometry, to promote the rapidity and accuracy of gas pressure determination.

1 GAS FLOWING LAW AROUND THE MANOMETRIC DRILL HOLE AND ITS MATHEMATICAL MODEL

1.1 *Gas pressure in coal seam*

The gas pressure in coal seam refers to the pressure of the gas contained in the coal seam. The determination method is to drill holes in the coal seam, bury piezometric tube, grout and seal holes, install pressure gage. The determination of the gas pressure under steady situation is the coal seam gas pressure.

1.2 *Gas migration law in coal seam*

According to the previous research on gas flow regularity, the migration law follows Darcy's law, that is, Laminar Flow—(Sun Peide, 1988).

In the actual case, when drilling to expose the seam, affected by factors, such as mechanical operation, the stress around the borehole changes, leading to the instability of the gas flow around the borehole in the seam. After a period of time when stress gets its balance, the gas flow is gradually stabilized in the radial unstable seam, Academician Zhou Shining thinks that the flow of gas in coal seam still obeys Darcy's law—(Zhou Shining & Lin Boquan, 1999).

1.3 *Model of gas flow in manometric borehole*

Coal is a kind of uneven double porous media made up of macro-cracks and micro-pores. Gas in coal seam remains in the macro-cracks and micro-pores in free state and adsorbed state. Once getting pressure relief, gas in coal seam begins to flow along the pores and fractures, while the absorbed gas is desorbed. Gas flow in Coal seam is actually a very complex process affected by many factors. In order to simplify the process, the coal seam gas flow model has the following assumptions—(Wang Xiaoliang, et. al, 2003).

1. The original gas in coal seam has even pressure distribution. As the permeability of the roof and floor of coal seam is much smaller than the coal seam, the rock mass of the roof and floor is, therefore, supposed to be gas-tight layers, completely free from gas;
2. Coal seam permeability and porosity is not affected by the change of gas pressure in coal seam;
3. Gas in coal seam consists of free gas and adsorbed gas, and it conforms to the Langmuir equation;
4. the gas field gas drilling flow can be considered as an ideal gas, and complies with the ideal gas state equation;
5. The gas is ideal. The gas flow in coal seams is laminar permeability in compliance to Darcy law;

With the above assumptions, the coal seam gas dynamic model of two-dimensional flow can be set up as follows:

$$\left(\frac{n}{p_0}+\frac{ab\rho_m k_a dr}{1+(bp)^2}\right)\frac{\partial p}{\partial t}=\frac{k}{2\mu p_0}\left(\frac{\partial^2 p^2}{\partial x^2}+\frac{\partial^2 p^2}{\partial r^2}\right) \quad (1)$$

Boundary conditions: coal wall, $p = p_0$; coal seams within coal wall, $p = p_a$.

The initial conditions: $t = 0$, $p = p_a$

The drill hole helps the discretization of the gas in its flow region in the coal seam. According toformula (1), the differential equation of the gas flow in the coal seam can be derived. Due to the gas pressure gradient around the drill hole, the coal seam gas always flows from where pressure is high to where pressure is low. That is, the gas will flow to the wall of the drill hole from a distance. The amount of gas emission per unit area $q(m^3/(m^3 \cdot s))$ on the wall of the drill hole can be obtained by Darcy Law as follows:

$$q=-\frac{k}{u}\frac{dp}{dx} \quad (2)$$

With the mathematical modeling of coal gas seepage, the discretizating of the gas by numerical method, and the using of FPRTAN language programming, the distribution of gas pressure and the law of gas emission can be calculated with analog equation under certain boundary conditions and initial conditions. Therefore, when the wall of the drill hole is suddenly exposed, the gas emission on the wall will sharply rise to the maximum amount, while with the exposure duration increasing, the gas pressure around the manometric hole decreases, the range of pressure decay enlarged, — the closer the gas pressure gradient to the drill hole wall, the larger the pressure; conversely the farther, the smaller. The longer the exposure duration is, the larger is the range of pressure decay, and the longer time it takes the hole to regain a gas pressure balance after hole sealing.

2 ACTIVE MANOMETRY

2.1 *Principles of active manometry*

The method of active manometry was promoted by academician Zhou Shining in 1980's. Active manometry is to aerate certain amount of air into the drill hole where coal seam is exposed or the manometric room through preinstall devices after having been sealed, so that the measuring time is largely shortened as the time to balance gas pressure is shortened. The compensate gas should be aerated into the drill hole after the drill hole is sealed. The gas out of the relief ring will start to flow toward the drill hole. The pressure relief ring in coal seam will not expand once the hole is drilled. The length of time for measuring the pressure is determined by the amount of gas needed to balance the pressure. If proper amount of gas is aerated into the drill hole in advance, the manometric speed will be accelerated. The compensate gas is used to make up for the gas emitted through the drill hole before it is sealed. Among CH_4, N_2, CO_2 or some other inert gases, according to the result of experiments, CO_2 has the highest adsorbability, CH_4 second, N_2 the lowest. For the sake of safety and the absorbtion-desorbtion performance of coal to gas, N_2 is a preferential choice.

2.2 *Manometric method with grouting hole sealing*

The hole is sealed with grouting. The materials for hole sealing is often cement paste, which expands rather than shrinks. The hole is sealed by compressed air grouting device or mud pump. This manometric method applies to gas pressure measure at any condition in the pit, in particular applies to the measure of gas in close distance coal seams and coal seams groups.

Grouting hole sealing is a widely-used way of hole sealing by now, which is especially adopted when the drill hole is too long. The sealing materials used are usually cement mortar or cement paste. The manometric devices often includes piezometer tube, inspection pipe, injection pipe, grouting pump, wood peg, baffle plate etc. (Fig 1.—Lan Zequan, et. al, 2009). If the execution condition is good enough, the inspection pipe and baffle plate can be omitted. Beside, considering the influence of water onto the gas pressure, the gas pressure value measured may need to be adjusted according to the following formula:

$$p_0 = p \pm 0.011 \times L_1 \sin\theta;$$

P_0: gas pressure in coal seam,
P: measured gas pressure, *MPa*;
L_1: Length of water in the piezometer pipe, *m*
θ: angle of the drill hole, minus sign for upward drilling, plus sign for downward drilling.

2.3 *Analysis of gas pressure balance*

In the gas room of the manometric drill hole, the two ends of the sealed hole bear the same amount of pressure when the gas pressure achieves balance. According to the law of mass conservation, when the gas pressure in the manometric drill hole reaches balance, the amount of compensate gas in the gas room is approximately equal to the amount of axial leakage of the sealed section. As is shown in the following formula:

—(Gao Jianliang & Hou Sanzhong, 2001)

$$2m\lambda_1(p_0 - p_1)G(F) = (2r_0 b + b^2)\lambda_2 \frac{p_1 - p_2}{L} \tag{3}$$

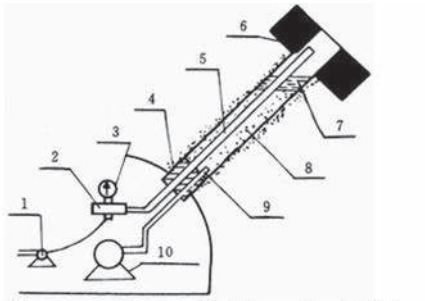

Figure 1. Schematic diagram of grouting hole sealing.

$$B = \frac{b(2r_0 + b)g}{2mLG(F)} \cdot \frac{\lambda_2}{\lambda_1}, \tag{4}$$

$$p_1 = p_a + \frac{p_0 - p_a}{B + 1} \tag{5}$$

B is dimensionless quantity, which can be defined as depressurization effect coefficient. The change of B value can accurately reflects the relations between the measured gas pressure value and the actual gas pressure value. As we can see from Formula (4), When B approaches 0, p_1 is close to the original gas pressure p_0. This is to assume that the hole sealing is fine and air-tight. When B approaches ∞, p_0 is close to the original gas pressure p_a. This is to assume the drill hole is unsealed and open wide.

From the expression of B, the value of B is inversely proportional to the length of sealed hole, the length of gas room m, and the manomentric time function, and in direct proportion to the radius r_0 of Manomentric drill hole r_0, the width b of non-elastic deformation around the drill hole b and the specific value of air permeability coefficient λ_2/λ_1. From what affects the B value, we can see that some of factors are very hard to control, such as λ_1, b. Therefore, the simplest way to accelerate the measuring pressure speed is to increase the length of sealed hole and decrease the capacity of the manomentry gas room.

Table 1.

Letter	Implication	Unit
m	The length of gas room	m
λ_1	The original coal seam gas permeability coefficient	$m^2/(MPa^2 \cdot d)$
p_0	The original gas pressure of coal seam	MPa
r_0	The radius of manometric drill hole	m
b	The inelastic deformation band width around the drill hole	m
p_1	Stable gas pressure value in gas room of manometric drill hole	MPa
$G(F)$	Manometric time function	—
λ_2	The permeability coefficient of the inelastic deformation zone of peripheral coal seam in the sealing section of the pressure hole	$m^2/(MPa^2 \cdot d)$
p_a	The press from the inner end part of manometric drill hole to the sealing part	MPa
L	The distance from the inner end part of manometric drill hole to the sealing part	m

2.4 *The approach to fast and accurate coal gas pressure determination—to shorten the exposure time of the drill hole, and to decrease the volume of the manometric room*

As is analyzed above, the gas flow field on the wall of drill hole can be approximately regarded as a steady one from the time when the hole is drilled to the time when the hole is sealed, in the course of which the gas pressure in the hole is much smaller than that original gas pressure in the coal seam. That is, the distribution curve of coal gas pressure in the drill hole is a logarithmic curve. The farther the distance is to the wall o drill hole, the higher the gas pressure is in the coal seam, which means the gas pressure gradient is large near the wall of drill hole; while the gas pressure gradient is small at the position far away from the hole wall. In the process of drilling, the inner wall of the drill hole in coal seam section is suddenly exposed, due to the increase of gas pressure gradient, the gas in the coal seam will rapidly rush out of the hole. The longer the exposure lasts, the larger amount of gas is emitted. Therefore, the hole should be sealed soon after the drilling work is finished to shorten the exposure time of the hole wall, so that the gas pressure in the gas room can rapidly achieve balance, and the menometric period is largely shortened.

When the manometric hole is sealed, with the accumulation of high pressure gas in the menometric room, the pressure gradient near the hole wall gets lower, the amount of gas emission per unit decreases as well. When the supplementary amount of gas in the menometric room Q_1 equals to the gushing amount of gas in the coal seam hole section Q_2, the gas pressure in the menometric room and in the coal seam stays in balance, and the gas pressure gradient near the hole wall is 0. That is,

$$Q_1 = Q_2 = S \times \int_0^T f(q)dt$$ In it:

Q_1 is the capacity of manometric room, including unsealed hole section and the lumen capacity of piezometer tube;
S refers to the exposed coal wall area of the coal seam hole section in the manometric room;
T stands for the time needed for the manometric hole room to achieve the pressure balance right after the hole is sealed;
$F(q)$ is the amount of gas emission per unit area, a function relating to time. Therefore, the capacity of manometric room should be decreased to on extreme, while the exposed area of the hole wall should be enlarged to the other, so that the manometric period is greatly shortened.

In order to shorten the exposure time of the drill hole wall and decrease the volume of the manometric room, the hole should be sealed right after the drilling work is finished, as long as the hole has pierced the coal seam. The radius of the piezometer tube and the length of the drill hole should both be shortened properly; the hole sealing should be stopped once it reaches the seam (roof) floor, or high pressure gas should be injected into the manometric room after the hole is sealed.

3 CONCLUSION

1. It is a growing trend to use active hole sealing to determine the gas pressure of the coal seam in the future gas pressure measurement.
2. The decrease of exposure time of the manometric hole and the volume of manometric room can help to shorten the manometric period. The manometric drill hole should be right as long as it pieces the coal seam, and the capacity of manometric room (including the radius of piezometer tube) should be decreased as much as possible. The drill hole should be sealed right after the drilling work finished, in order to shorten the exposure time of the hole wall. Or high pressure compensation gas should be injected into the room. The gas pressure in the coal seam can be rapidly determined.
3. The key for manometric accuracy lies on the quality of sealing. With the manometric room and tube ready, to inject cement paste (or other hole sealing materials) into the drill hole can effectively prevent the tiny fractures around and on the inner wall of the hole. Therefore, the densification of the sealed hole section will largely increase the quality of hole sealing and accuracy of manometry.

Study on effect of gas adsorptive constant under electro magnetic fields exerted

Li Zhang, Xueqiu He, Jianhua Yue & Enyuan Wang
College of Energy Resource and Earth Science, China University of Mining and Technology, Xuzhou, Jiangsu, China
Research Center of State Administration of Work Safety, Beijing, China

ABSTRACT: Experimental study was done on the effects of electromagnetic fields on gas adsorptive constant a/b of different coal rank. The research results show that the electromagnetic fields almost have no effects on gas adsorptive constant a, but can reduce adsorptive constant b obviously. Adsorptive constant b decreases with voltage and frequency of electromagnetic field exalting. The exerted electromagnetic fields can reduce the capability of coal adsorption to gas and gas adsorptive volume.

1 INSTRUCTIONS

Gas accident is the main disasters of coal mines, and it is also called "the first killer" of coal mines. The direct reason why both gas explosion and outburst of coal and gas accident took place are there is a plenty of adsorbed gas in coal seams, 90 percent of gas in coal seam exists with the adsorbed form. Characteristics of gas adsorption in coal are one of basis for summarizing the law of gas explosion and forecasting and preventing gas accident. Studying on characteristics of coal adsorption to gas is help to expounding mechanism of gas adsorption and emission law. The purpose of the current study is to determine the adsorption properties of different coal by using electromagnetic fields exerted in order to go deep into research mechanism of coal adsorption/ emission to gas. The result of this study will lead to a better understanding of prevention gas accident and hence will be provide a new method to reducing adsorptive gas content.

2 EXPERIMENT

2.1 *Coal samples and experimental methods*

Coal samples are taken from Renlou coal mine and Yangquan coal mine. Coal samples are crashed into particles in the size of 0.25 mm to o.5 mm in diameter. Experiments are carried out by use of adsorption and emission apparatus made by China University of Mining & Technology, and an electromagnetic field generator is used to exert alternative electromagnetic field on coal particles containing gas (Zhang 2002). The setup of the experimental system is show in Fig. 1. The effect of electromagnetic field exerting model on gas adsorptive constant is tested under conditions of different voltage or frequency.

The experiment is composed of four steps, namely, gas pumping, lower pressure gas adsorption, high pressure gas adsorption and gas emission measurement. Experiments are conducted when alternative electromagnetic field is exerted on coal containing gas in the last three steps to study gas adsorptive constant *a*/*b*. The gas used is methane, and coal samples are anthracite and bituminous coal.

The alternative electromagnetic field is exerted on coal particles in the last three steps with fixed parameters which are voltage of 500 to 1200 V, and frequency of 0.54 to 1.58 MHz. When alternative electromagnetic field is exerted in the second step or the third step, it is exerted all the time. When it is applied in adsorptive experiment, the operation are as following: First, the coal samples is pumped to vacuum, then let one atmosphere methane absorb into coal samples until it reach to adsorptive balance, meanwhile record adsorptive amount changing with time. When the measurement of high

Figure 1. Experimental Instrument.

pressure gas adsorption and emission, operation are as following: first, the coal samples is pumped to vacuum, then filled in certain pressure methane until it reach to adsorptive balance, then made the adsorptive pressure fall down to certain pressure several times reaching to the new adsorptive balance until to one atmosphere, meanwhile record every emission amount changing with time. Gas emission experiment must be kept the adsorptive balance pressure same, otherwise it has no comparable. The research work is carried out to study effect of gas adsorptive constant *a*/*b* in which a series of experiment is repeated with electromagnetic field exerted.

2.2 *Experimental results and analysis*

When alternative electromagnetic field is exerted in adsorptive step, typical experimental result is shown in Figure 2, Figure 3, Figure 4 and Figure 5 in which y axis represent gas adsorptive quantity calculated indirectly from every ton of coal adsorptive quantity and x axis represent adsorptive balance pressure. Figure 2 and Figure 3 show the adsorptive results which the volt of alternative electromagnetic is fixed 1000 v, but the frequency is changed. In Fig. 2 coal sample is taken from Yangquan coal mine which the coal is anthracite. In Fig. 3 coal sample is taken from Renlou coal mine which the coal is bituminous coal. Both in Fig. 2 and Fig. 3, curve 1 represent the characteristics curve of gas adsorption without electromagnetic field, and curve 2 is electromagnetic field which voltage is 1000 volt and frequency is 0.54 MHz. Curve 3 is electromagnetic field which voltage is 1000 volt and frequency is 0.73 MHz, Curve 4 is electromagnetic field which voltage is 1000 volt and frequency is 1.11 MHz, curve5 is electromagnetic field which voltage 1000 volt and frequency is 1.58 MHz.

Figure 4 and Figure 5 show the adsorptive results which the frequency of alternative electromagnetic is fixed 0.54 MHz, but the volt is changed. Fig. 4 coal samples is the same one with Fig. 2, and Fig. 5 coal samples is the same one with Fig. 3. Both in Fig. 4 and Fig. 5, curve 1 represent the characteristics curve of gas adsorption without electromagnetic field, and curve 2 is electromagnetic field which voltage is 500 volt and frequency is 0.54 MHz. Curve 3 is electromagnetic field which

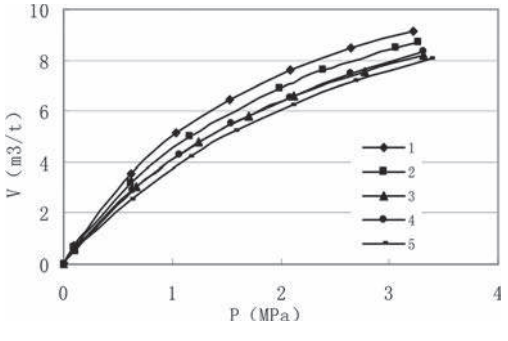

Figure 3. Gas Adsorption frequency Characteristics of Renlou coal samples.

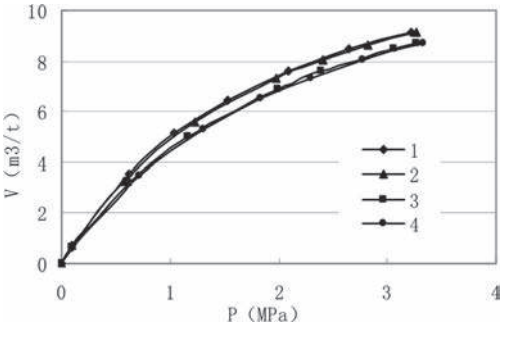

Figure 5. Gas emission frequency Characteristics of Renlou coal samples.

Table 1. Adsorptive constant of experimental coal samples.

Frequency (MHz)	Yangquan coal sample			Renlou coal sample		
	a	*b*	*r*	*a*	*b*	*r*
No exerted	46.1606	1.1596	0.9936	14.7500	0.5100	0.9945
0.54	47.0168	0.9679	0.9975	14.7168	0.4435	0.9959
0.73	45.0000	0.9117	0.9954	14.4301	0.3975	0.9967
1.11	46.2532	0.8213	0.9968	15.1132	0.3665	0.9978
1.58	46.1461	0.7210	0.9949	15.6303	0.3160	0.9947

Table 2. Adsorptive constant of experimental coal samples.

Volt (V)	Yangquan coal sample			Renlou coal sample		
	a	*b*	*r*	*a*	*b*	*r*
No exerted	46.1606	1.1596	0.9936	14.7500	0.5100	0.9945
500	46.8523	1.1367	0.9964	14.9300	0.4875	0.9973
1000	47.0168	0.9679	0.9975	14.7168	0.4435	0.9959
1200	46.1577	0.9582	0.9941	15.0132	0.4165	0.9938

voltage is 1000 volt and frequency is 0.54 MHz, curve4 is electromagnetic field which voltage 1200 volt and frequency is 0.54 MHz.

It can be seen clearly from the above figures that the gas adsorption characteristics curves with electromagnetic field are different from that without electromagnetic field. The main difference is that gas adsorptive quantity is reduced in experiments with electromagnetic field contrasting with that without electromagnetic field. Gas adsorptive amount is abated with both voltage and frequency of electromagnetic field lift. Electromagnetic field effect can slack amount of coal adsorption to gas and increase. Electromagnetic field effect can debase ability of coal adsorption to gas (He & Liu 1995, Zhang 1999, 2000).

2.3 *Adsorptive constant Analysis*

When test temperature is 30 °C, test gas is methane, the two kinds coal samples adsorptive constant is shown in Table 1 and Table 2.

From the above tables can be learn, the electromagnetic field have effect on gas adsorptive constants *a*/*b*, electromagnetic effect of adsorptive constant *a* is inconspicuousness. Adsorptive constant *b* decreases with voltage and frequency of electromagnetic field exalting.

3 MECHANISM ANALYSIS

Coal adsorption to gas is physical adsorption. Under high pressure and at certain temperature it is follow the famous 1 angmuir equation as following (Gu 1994):

$$Q = \frac{abP}{1 + bP} \tag{1}$$

Where: T is temperature, °C; P is adsorptive balance pressure, MPa; Q is adsorptive gas content under P pressure, ml/g or (m^3/t); *a, b* are Langmuir adsorptive constant, *a* is saturation adsorptive content, ml/g or (m^3/t); *b* is adsorptive constant, MPa^{-1}.

A is saturation adsorptive content of coal. It is decided mainly by metamorphic degree of coal, bore rate of coal, and other own characteristics of coal, and it has very little influence with outside. So electromagnetic field can not change constant *a.* Constant *b* is decided by temperature and surface potential well. The higher the temperature is, the less the value *b* is, and the less adsorptive gas content is. On the contrary, the lower the temperature is, the larger the value *b* is, and the more the adsorptive gas content is. For the depth of surface potential well, the deeper the surface potential well is, the more the adsorptive gas content is. On the contrary, the shallower the surface potential well is, the less the adsorptive gas content is. The electromagnetic field can make temperature high and reduce depth of surface potential well, so it can reduce the constant *b*.

4 CONCLUSIONS

Coal adsorption to gas under electromagnetic field is physical adsorption. The gas adsorptive capacity

of coal is abated for the agency of electromagnetic field. When the frequency of electromagnetic field is changeless, the capacity of coal adsorption to gas is reduced with the voltage of electromagnetic field lifted. When voltage of electromagnetic field is changeless, the capacity of coal adsorption to gas is reduced with the frequency of electromagnetic field lifted. An alternative electromagnetic field can reduce the amount of gas adsorptive constant b. Thus it is possible to reduce the elastic potential energy of gas and prevent gas accident.

Hazard prediction and prevention of rock burst in island working face

S.S. Guo
State Key Laboratory of Gas Disaster Monitoring and Emergency Technology, Chongqing, China
Chongqing Research Institute of China Coal Technology Group, Chongqing, China

ABSTRACT: When the mining depth is larger, the stress concentration is at a very high level at the island working face and its surrounding roadways. The risk of rock burst is higher coupled with the influence of the geological tectonics. The article analyzed coal and rock physical and mechanical properties of 2–228 island working face in Liyazhuang coal mine, determined the energy source of rock burst using micro seismic monitoring technology, determined the hazardous area and level of rock burst, formulated the corresponding prevention measures, and to achieve the safety mining of at the island working face. The article provides a beneficial reference for the same conditions of the mine mining area and other similar mine island working face.

1 INTRODUCTION

The rock burst disaster in our country has become increasingly serious with the increase of mining depth. Because of the complexity and instantaneous burst of rock burst, prediction and prevention the rock burst disaster has always been a problem in safety production of coal mine (He Manchao et al. 2005, LI T 2007, Pan Liyou 2006). For high gas coal mine island working face of large mining depth, under the coupling of high ground stress, high gas and geological structure, the mechanism of coal and rock dynamic disaster is more complicated, which is difficult to predict and prevent. According to the actual situation of 2–228 island working face of Liyazhuang coal mine, this article analyzed the mining technical conditions such as coal and rock physical and mechanical characteristics, stress field distribution and gas parameters. Combined with monitoring technology, this article also analyzed the causes of dynamic phenomenon and sources of energy, predicted disaster degree and the range in advance, and taken appropriate control measures to achieve the safety mining of at the island working face.

2 PRODUCTION TECHNOLOGY CONDITIONS OF 2–228 ISLAND WORKING FACE

The 2–228 working face of Liyazhuang coal mine is located in the second mining area on the left, which is an island working face both sides of the section has been worked out (As shown in Fig. 1). The upper side of 2–228 working face is 2–220 goaf, equipped with 20 m pillar; the underside of 2–228 working face is 2–224 goaf, equipped with 20 m pillar. 2–228 working face is about 650 m underground. The strike length of 2–228 working face is about 630 m and tendency length is about 130 m. The thickness of main mining no. 2 coal seam is about 3.16 m on average with 2 layers of dirt band (mainly mudstone, carbonaceous mudstone). The Coefficient of the coal seam is 1.5. The average angle of the coal seam is 6°. The structure of the coal seam is complex. The immediate roof of no. 2 coal seam is sandy mudstone (0–2.87 m), basic roof is medium-fine sandstone (2.1–4 m), direct bottom is siltstone (1.4–3.0), and basic bottom is mudstone (1.5–1.7 m). Affected by factors of high original rock stress, mining stress concentration

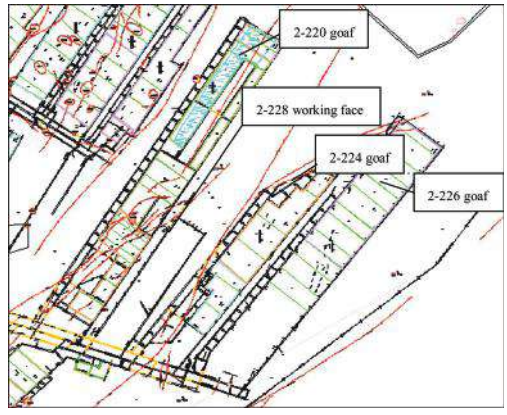

Figure 1. The arrangement plan of 2–228 island coal face.

and gas, the no. 2 coal seam appears rock burst and jet orifice phenomenon, which is a serious threat to safety production.

3 PHYSICAL AND MECHANICAL PARAMETERS, AND THE EVALUATION OF THE ROCK BURST ORIENTATION OF COAL AND ROCK

Over the years, domestic and foreign scholars did lots of experimental study on rock burst, and gained valuable research results (Pan Jienan et al. 2005, Zou Deyun et al. 2004, Zhao Yixin et al. 2007, Pan Jienan 2006, Su Chengdong 2004, Feng Zengchao et al. 2003, Pan Yishan et al. 2003, Li Shulin 2001) They thought there must have two kinds of factors to cause rock burst: (1) Stress conditions. In-situ stress is the basic force mine dynamic phenomena, which belongs to the external factors. (2) Mechanical properties of coal or rock. Mechanical properties of coal or rock are important internal factors caused Rock burst. The relationship between the risk of rock burst and the structure characteristics of coal and rock are very close. The impact tendency of coal and rock characteristics is the inherent properties of coal (Pan Jienan et al. 2005, Zou Deyun et al. 2004). The impact tendency index of coal and rock includes dynamic failure time, elastic strain energy indices, impact energy indicators, brittleness coefficient, and so on.

In order to determine the impact tendency of 2–228 island working face, we took the coal and rock sample in coal seam and roof of 2–228 working face, and measured impact tendency of coal and rock sample according to the standard evaluation method of coal and rock impact tendency.

Processing production of coal sample and physical mechanical parameters test are in strict accordance with the provisions of *Measurement method of coal and rock physical and mechanical properties* (GB/T 23561–2009), and *Measurement method of coal seam impact tendency classification index* (MT/T 866–2000). The experiment determined natural apparent density, compressive strength, consistent coefficient, elastic modulus, deformation modulus, wave velocity, rock burst energy index, elastic energy index, dynamic failure time, and other parameters. The determination results as shown in Table 1.

Known from the analysis of Table 1, compressive strength and elastic modulus of coal samples are medium. According to the comprehensive results analysis of rock burst energy index, elastic energy index and dynamic failure time, no. 2 coal seam of 2–228 island working face has medium impact tendency. Sandstone and medium grained sandstone in coal seam roof have high compressive strength and resistance to deformation ability, coefficient is 12.6 and 19.0 respectively, and belongs to the class hard rock. The thickness of Sandstone is about 4.6 m, which bending strength is 23.42 MPa, modulus of elasticity is 34.5 GPa, is 650 m depth from surface. The bending energy index of sandstone is 7.6 kJ, and elastic energy index UWQ ≤ 10 kJ, which belongs to no impact tendency rock with reference to *the method for determination of the rock impact tendency classification index* (Yang Zhiguo et al. 2009). The compressive strength of sandy mudstone in coal seam roof is medium and coefficient is 5.9, belongs to medium hard rock and no impact tendency rock.

Table 1. Test results summary of coal and rock physical and mechanical parameters.

name of rock / parameters	coal samples		sandstone		medium grained sandstone		sandy mudstone	
	minimum~maximum	mean	minimum~maximum	mean	minimum~maximum	mean	minimum~maximum	mean

4 THE OVERBURDEN STRESS DISTRIBUTION OF 2–228 ISLAND WORKING FACE

We simulated the overburden stress distribution of 2–228 island working face by using numerical simulation software FLAC^{3D}. The simulation range for the 2–228 island working face is: length 600 m, tend to range from 2–220 goaf to 2–224 goaf. The direction of excavation is along with working face advancing direction. The simulation result shown in Fig. 2.

Through the Fig. 2 stress distribution in three-dimensional figure, we can see the pressure on either side goaf of the 2–228 working face have been relieved, and the stress of 2–228 island working face and coal pillar concentrated, especially on both sides coal pillar of working face and near security exit.

We intercepted stress distribution along the X axis section of 2–228 working face, as shown in Fig. 3. The internal stress of 2–228 island working face (vertical in-situ rock stress) is 14 MPa, overburden maximum stress close to 24 MPa, and the abutment pressure in front of the working face stress reached more than 20 MPa. Working stress concentration caused by mining at around double the original vertical stress. As the isolated island working face, the 2–228 working face under the concentration of stress is bigger, near the coal pillar or fault, stress concentration threshold is reduced, it is prone to dynamic disasters.

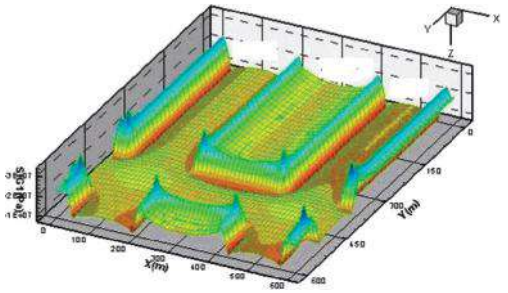

Figure 2. Stress distribution in three-dimensional of 2–228 Island working face.

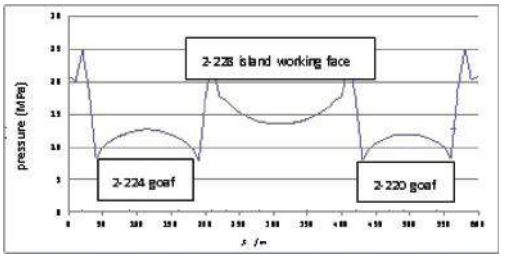

Figure 3. stress distribution along the X axis distribution of 2–228island working face.

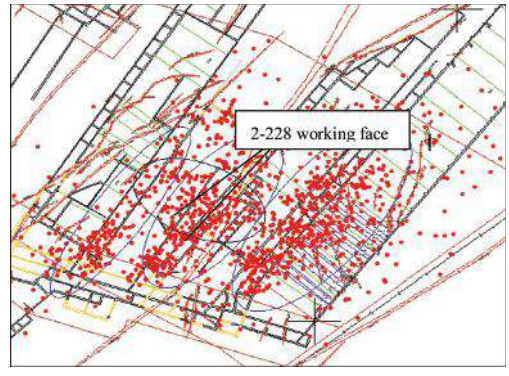
5 MICRO SEISMIC MONITORING OF PERCUSSIVE ROCK BURST SOURCES AND ENERGY

The substance of micro seismic events is a form of series of dynamic evolution caused by surrounding rock stress, strain, deformation, rupture and instability and failure. In the process of coal mining stope advance, coal and rock mass in front of the working face are divided into the elastic zone, plastic zone and plastic zone, which corresponds to the original stress zone of mining abutment pressure, peak stress zone and stress reduction zone. In high stress area of coal and rock, under the mining activities of disturbance, coal and rock stress boundary conditions and original rock stress change, stress release caused the fracture of coal and rock fracture micro seismic events. So the micro seismic events can reflect the high stress of coal and rock mass and rock ultimate strength area.

Seismic technology is a kind of monitoring of mine coal and rock dynamic disaster regional prediction method, which can monitor coal and rock seismic activity in real time, continuous and online, and it becomes one of the important means of forecasting rock burst disaster and mechanism research in coal mine (He Manchao et al. 2005, LI T 2007, Pan Liyou 2006, Yang Zhiguo et al. 2009). On the basis of analysis of coal roof and floor rock physical and mechanical properties and stress distribution of 2–228 island working face, we arrangement 11 points in no. 2 mining area of Liyazhuang coal mine and continuous monitor for three months With SOS micro seismic monitoring system. Seismic source localization plan is shown in Fig. 4.



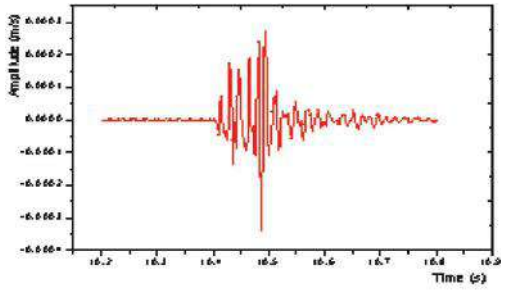


Figure 4. Seismic source localization plan.

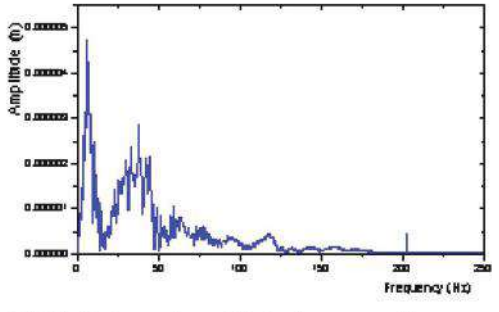

We monitored 1207 times shock in no. 2 mining area within 3 months, as shown in Fig. 4. Micro seismic occurred, which indicated that regional coal pillar and roof and floor of 2–228 working face has burst, the place of surrounding rock in a state of flux. Micro seismic source distribution mainly concentrated in the 2–228 working face, coal pillar between 2–228 working face and 220 goaf, coal pillar between 2–228 working face and 2204 goaf, in the basic between 20 m upper area and 50 m underside of 2–228 working face. This suggested that the area under the condition of high stress by working face mining disturbance, damage and the roof and floor strata occurred in the form of seismic performance.

Micro seismic monitoring system recorded seismic energy of the 2–228 working face is concentrated in between 10^2~10^5 j. The article tried to analyze the relationship between seismic energy and the occurrence of rock burst based on. 9 measuring point laid out in 2–228 conveyance road which detected in more than 10^3 j of energy of seismic waveform and spectrum characteristics, as shown in Fig. 5.

As shown in Fig. 5, the rock burst which vibration energy is greater than 10^3 j, its amplitude of main vibration speed is between 0.2×10^{-4}~5.0×10^{-4} m/s, and duration time of signal is between 600~1800 ms. The attenuation is fast, and the higher the energy, the longer the duration. Look from the frequency spectrum, signal distribution between 0~160 Hz, frequency band is wide, between 10~75 Hz. This from a side show that the 2–228 island working face has the possibility to occur rock burst, fault activation, goaf roof fracture, roof fracture of cutting hole, and other factors are the main cause of micro seismic signals.

(b) No.9 channel amplitude-frequency figure

Figure 5. Part micro seismic events waveform and spectrum graph of energy is greater than 103 j.

6 PREVENTION AND CONTROL OF ROCK BURST

In view of the rock burst occurred in zoning and characteristics in 2–228 island coal face of Liyazhuang coal mine, it shows prevention and control of rock burst should follow the following principles: (1) Try to avoid the high stress area formation or work in high stress area; (2) Ensure maximum in-situ stress direction parallel mining or tunneling; (3) Expand the scope of stress release, in order to reduce the stress concentration and stress release rate; (4) Control conditions of coal seam storage energy; (5) Control of roof sudden release of energy and load; (6) Minimize construction to the effect of percussive ground pressure. According to the fact that 2–228 island working face has been formed, it should take the following measures to prevent and control rock burst:

1. Construct gas drainage unloading borehole in mining-coal bed, and drill before mining. The main purpose of the construction of drainage hole is: On the one hand, using the drilling pressure relief effect. The essence of the borehole pressure relief is under high stress conditions, using of accumulated elastic energy to subvert the borehole in coal seam coal body around, make coal unloading, releasing energy, eliminate risk impact. On the other hand, using gas release of coal seam gas potential, increase the strength, thereby increasing resistance to the potential of percussive ground pressure.

   Drainage unloading borehole can adopt positive parallel or oblique parallel hole drilling way (Fig. 6). Borehole spacing is between 5~7 m and 110 m deep.
2. Coal seam water injection. Coal seam water injection is through increasing the moisture content of coal seam or water saturation in coal seam to change state of coal and rock deformation, make sure the failure does not occur so as to prevent the occurrence of rock burst. Arrangement water injection hole drilling in return airway along the coal seam strike, water injection hole drilled parallel to the working face, and separation distance is 12 m. The diameter of water injection hole is 75 mm, and depth

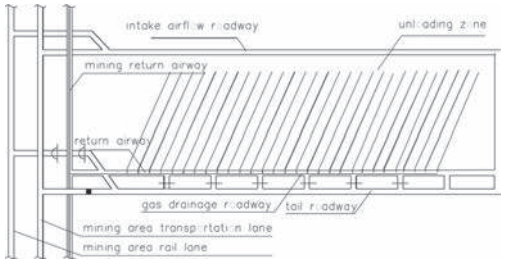

Figure 6. Drainage unloading borehole layout diagram.

is 60 m. Water injection of every single hole is about 3056 t. Injection time should not less than 30 days. Water injection pressure is 6~12 Mpa.

7 CONCLUSIONS

1. Through the measurement of coal and rock physical and mechanical parameters, the no. 2 coal seam of Liyazhuang coal mine has medium impact tendency and no impact on the roof strata. Due to stress concentration, hazard of 2–228 island working face is rock burst risk, and the rock burst hazard degree is weak shock hazard.
2. Through analysis of overlying rock stress distribution, stress concentration regions of 2–228 island working face mainly concentrated on both sides coal pillar of working face and near security exit.
3. Stress concentration, fault activation, goaf roof fracture, goaf roof fracture directly, roof fracture of cutting hole are the main reasons causing weak rock burst hazard of 2–228 Island working face.
4. Through the construction of drainage in the coal seam pressure relief drilling and extraction, and water injection before mining, can effectively reduce the chance of rock burst risk.
5. Liyazhuang coal mine should adjust mining sequence, mining area and layout of the working face, realize coal pillar mining, and avoid formation of stress concentration.

School of Resources and Safety Engineering, China University of Mining and Technology (Beijing), Beijing, China

ABSTRACT: With the contradiction between resource depletion, environmental disruption and economic development becoming increasingly prominent, mining under buildings, railways and water has drawn more and more attentions. Filling mining which ensures safe production conditions can effectively exploit the coal resources under buildings, railways and water. Mining under villages in Xuecun coalmine is analyzed in this paper, combined with the existing mining under buildings methods, the scheme of mining with paste-like filling under villages was confirmed. The system and process of paste-like filling were studied. The economic and social benefits of mining with paste-like filling under villages were comprehensively analyzed, which could provide guidance for production practice in Xuecun coalmine.

1 INSTRUCTIONS

According to the incomplete statistics of key state-owned coal mines, the amount of coal resources under buildings, railways and water are 13.79 billion tons, with the amount of coal resources under buildings are 8.76 billion tons, that accounts for over 60% of the total amount of "three under" coal resources. At the same time, with the demand of industrial production for coal resources increases and mining area coal resources are drying up, to free coal resources under buildings, railways and water is imperative (Zhang Huaxing 2011).

Based on the specific geological conditions of Xuecun coalmine and actual distribution of surface villages, to put forward a suitable mining method for coal resources under villages in Xuecun coalmine, with economic, efficient and safe mining scheme selected, has important economic value and social significance for coal mining under villages.

2 COAL UNDER THE VILLAGES AND MINING CONDITIONS

2.1 *The village overview and coal pillar situation*

Dashucun villages are located in the border of Xuecun coalmine northern coal field and Dashucun coal field, Dashucun industrial square pillar is in the east, Dongzhuang coal pillar is in the west and in the south is Xuecun coalmine 6th panel. Dashucun village pillar stretches across two coal field in the north and south. The strike length of coal pillar is about 1015 m, the incline length is about 1010 m, and the coal pillar covers an area of 1.025 km^2. The majority of housing constructions is bungalow or brick masonry structure. The ground elevation is about +206.2 m ~ +222.2 m. The mining coal seam is 2# coal seam (big coal) and 4# coal seam (yeqing coal), 2# coal seam belongs to the stable seam, which thickness is about 5.5 m; 4# coal seam belongs to the comparatively stable seam, which thickness is about 1.3 m. The liner distance between ground and 2# coal seam roof is about 426 m~625 m, the layer spacing between 2# and 4# coal seam is 33 m.

2.2 *Mining coal seam reserves*

The minable seam of Dashucun coal pillar are 2# and 4# coal seam, the coal reserves is shown in Table 1. 4# coal seam as the liberation seam would be mined first, which plan with caving mining method had passed the argument. The paper is gong to analyze the mining scheme of 2# coal seam.

Table 1. Mining coal reserves.

	Inclined area	Coal thickness	Recoverable reserve
Coal seam	m^2	m	10^4t
Yeqing coal (4#)	956237	1.3	174
Big coal (2#)	956237	5.5	736.3
Total			910.3

* Coal bulk density is 1.4 t/m^3

3 STUDY ON TECHNOLOGY OF MINING THE VILLAGES PILLAR WITH PASTE-LIKE FILLING

3.1 *Mining methods under buildings*

Mining under buildings has a long history and has much successful experiences. In addition to the village relocation, more typical methods include strip mining method, harmony mining method, overburden rock abscission layer grouting method and goaf filling mining method (Huang Yucheng, et al. 2003).

1. Strip mining method. The method is a kind of effective mining technology for controlling the surface subsidence. The surface subsidence coefficient of strip mining method is small, usually is 0.05~0.2. The main disadvantages of strip mining method are the low recovery rate which generally is 30%~60%, the high tunneling rate, the working face moving frequently and the production efficiency is low.
2. Harmony mining method. Fundamentally, the harmony mining method can also protect the surface building from damage caused by uneven surface subsidence, but it can't control the surface subsidence effectively and has difficulty especially for the mining under a wide range of urban buildings.
3. Overburden rock abscission layer grouting method. From the perspective of the engineering practice result, the overburden rock abscission layer grouting technology can effectively delay the speed of surface subsidence under the condition of certain strata, the surface subsidence can reduce about 30%~70%, but at the moment, the knowledge of temporal and spatial dynamics distribution law of abscission layer is still not enough in-depth and thorough.
4. Goaf filling mining method. By filling method can greatly reduce the surface subsidence and protect the subsidence of surface buildings effectively, at the same time, with the filling mining method, we can improve the coal recovery rate of coal pillar under villages, make full use of the coal gangue waste, and reduce the environment pollution.

3.2 *Determination of filling mining technology*

Based on the following several factors, for Dashucun coal pillar mining confirms to adopt the filling mining method.

1. 4# coal seam of Dashucun coal pillar had determined to adopt caving mining method, the surface deformation caused by mining had a certain impact on the village. In order to reduce the damage and influence of coal mining under the village and produce more coal resources, adopting filling mining method could be more effective.
2. Filling mining technology is comparatively mature, adjacent Xiaotun coalmine had taken advantage of filling mining method to exploit the safety coal pillar under Nanwangcun, the coalmine has been equipped with the appropriate filling mining technology and practical experience.

Nowadays, there are four kinds of filling mining technologies in coalmines: waste rock filling, paste filling, high water filling and paste-like filling.

Paste-like filling slurry concentration is controlled at 75%~79%, the slurry liquidity performs well and is beneficial to roof-contacted filling. Additionally, the slurry quality control and delivery of paste-like filling by pump are more convenient, the probability of blocking pipe incidents is low and the stability and reliability of the system work better. The new pattern of mining with paste-like filling can organically combine with the utilization of industrial solid waste and the control of surface subsidence to realize low degree of surface damage, high utilization rate of resources and less waste products, which shows the connotation and characteristics of resources green mining (Huang Yucheng, et al. 2013). Therefore, the paste-like filling process is selected.

2# coal seam thickness is 5.5 m, given the filling mining technology level, mining 2# coal of Dashucun village pillar should adopt slicing and filling scheme: the higher slice mining thickness is 2.8 m and the lower slice mining thickness is 2.7 m. The mining sequence is that filling mining the higher slice first, then filling mining the lower slice.

Comprehensive consideration about the coal production of filling working face and the existing filling equipment capacity matching, the width of filling mining working face is determined to 80 m, the first mining face of higher slice is filling mining 2#-1 face, subsequently, working faces are seriatim arranged northwards, after the completion of those working faces mining, then new working faces are seriatim arranged southward for mining. Working faces layout is shown in Figure 1.

3.3 *Filling station and filling drill*

Position of filling station: By comprehensive consideration of Dashucun coal pillar and the ground can be used to layout the filling area, the surface filling station is arranged in the south of Dashucun about 200 m faraway, the geographical coordinates of (X, Y) = (23529, 46505), as shown in Figure 1.

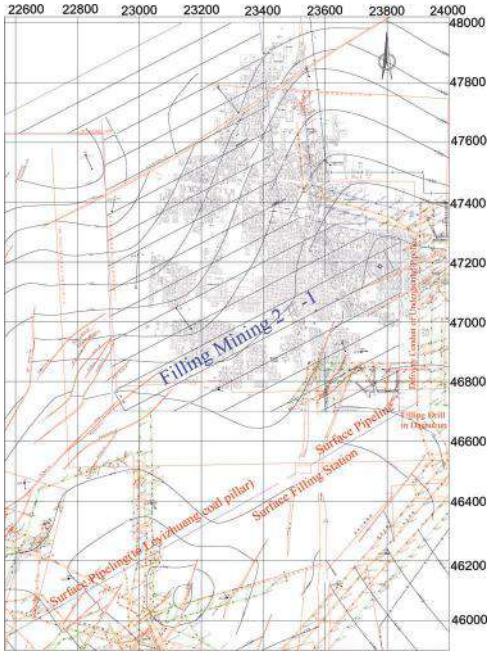

Figure 1. Working faces layout and the surface position of filling station.

Layout of filling drill: Considering the filling station layout and filling pipeline, the filling drill is arranged in the southeast of filling area, above the 8# guideline of northeast roadway, the geographical co-ordinates of (X, Y) = (23898, 46730).

3.4 *Design capabilities of filling system*

Composition of filling materials: As the concentration of the paste-like filling is 78%, the corresponding ratio of slurry includes 6% cementing material, 52% coal gangue, 20% fly ash and 22% water.

Capability of filling system: the capability is mainly considered to the coal production of filling working face and the existing filling equipment capacity matching. To design a single filling working face with an annual coal output of 360000 t/a, an annual working day is 330 days, then the working face production is 1100 t per day. The coal density is 1.4 t/m^3, and the filling volume is 786 m^3 per day. The filling valid time is 6 h per class, and the work capability of filling system needs to be 130 m^3/h. Therefore, the filling capability of filling system is 130 m^3/h and the designed capability is considered 150 m^3/h. With the density of filling slurry for 1900 kg/m^3, the calculation of filling materials consumption is as shown in Table 2.

Table 2. Consumption calculation table of filling materials.

Item		Quantity
Filling quantity	Ability of filling system/m^3/h	150
	Class filling quantity/m^3/class	786
	Class effective fill time/h/class	6
Material ratio	Cementing material/kg/m^3	114
	Coal gangue/kg/m^3	988
	Fly ash/kg/m^3	380
Consumption of filling materials	Water/kg/m^3	418
	Per hour consumption Cementing material/t/h	17.1
	Coal gangue/t/h	148.2
	Fly ash/t/h	57
	Water/m^3/h	62.7
	Per class consumption Cementing material/t/h	89.6
	Coal gangue /t/h	776.6
	Fly ash/t/h	298.7
	Water/m^3/h	328.5

3.5 *System composition of filling preparation station*

There are four kinds of materials used in paste-like filling, which are fragmentized coal gangue, fly ash, special cement and water. The process of filling is as follows (Sun Henghu, et al. 2002):

1. At first, to process the fragmentized coal gangue.
2. In the next place, mixing the coal gangue, fly ash, special cementing material and water in proportion to make into paste-like slurry.
3. Then, through filling pump, the paste-like filling slurry is transported to the underground working face to filling confined space of mined-out area which is formed by hydraulic filling support with secondary isolation measures.

The entire filling process flow is as shown in figure 2, which can be divided in to four basic links as waste rock broken, slurry preparation, pipeline pumping and filling body building.

Therefore, the structure of filling preparation station system mainly includes the subsystems of coal gangue broken, filling slurry preparation, pipeline pumping and the system of measurement and control.

4 GROUND DEFORMATION PREDICTION OF FILLING MINING

4.1 *Design capabilities of filling system*

Ground movement parameters: According to the filling mining technology data of neighboring

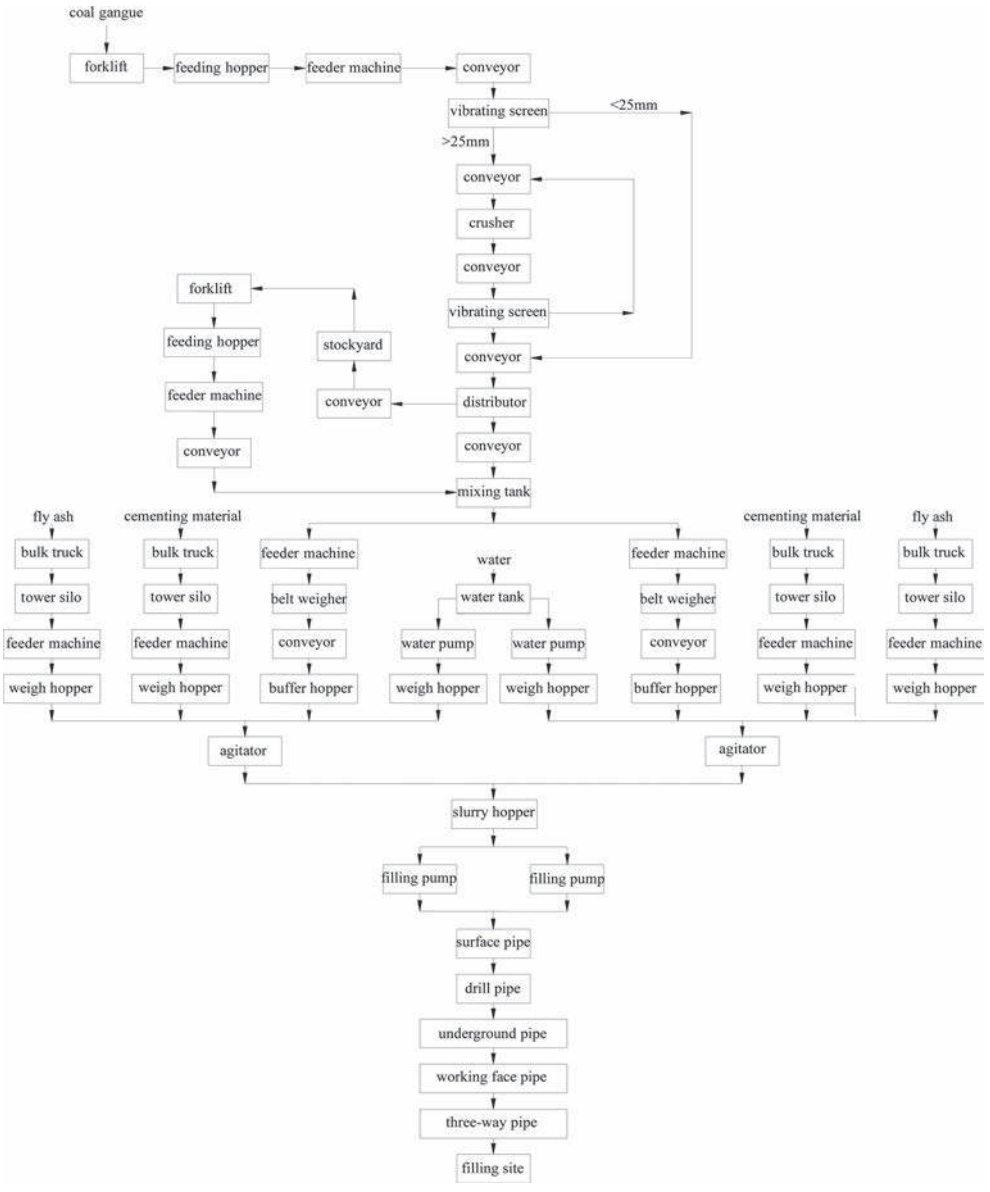

Figure 2. Process flow of paste-like filling system.

Xiaotun coalmine, the filling ratio of slicing and filling method can be 90%, then the surface subsidence co-efficient q will be 0.08, here to take q = 0.1. Determining the basic prediction parameters of surface movement and deformation is as shown in Table 3.

Housing deformation resistance parameters: According to the measurement of surface movement and deformation, housing capability of resistance to compression is stronger than resistance to tension. Considering the sensitivity of mining under villages, in the study of the scheme, the building ability to resist deformation is reduced. Based on computation and building deformation situation analysis, the critical deformation value of the building damage level are as follows:

1. I-level damage, compression deformation ≤2.0 mm/m, tensile deformation ≤1.5 mm/m;
2. II-level damage, compression deformation ≤3.5 mm/m, tensile deformation ≤3.0 mm/m.

Table 3. Basic prediction parameters of surface movement and deformation.

Coal seam	Mining method	q	Coal thickness m	b	k	tgβ	S1	S2	S3	S4
Yeqing coal (4#)	Caving mining	0.8	1.3	0.3	0.6	2.2	0	0	0	0
Big coal (2#)	Filling mining	0.1	5.5	0.3	0.6	2.2	0	0	0	0

*q – subsidence coefficient; b – horizontal movement coefficient; k – coefficient related to lithology; tgβ – tangent of major influence angle; S – deviation of inflection point.

Table 4. Situation of surface maximum deformation and buildings damage.

	Wi/ mm		εs+/ mm/m	εs−/ mm/m		εt+/ mm/m		εt−/ mm/m	
Deformation Value	1560	2.62	2.92	–2.79	–2.73	–2.29	2.31	–2.4	–3.04
Location	West of Dashu-cun	North-east of Dashu-cun	Southeast corner of Dashucun	Southeast of Dashu-cun	West of Dashu-cun	North-east of Dashu-cun	North-east of Dashu-cun	East of Dashu-cun	South of Dashu-cun
Level		II	II	II	II	II	II	II	II
Area/m²		53817	26576	34866	32404	21442	28673	10191	56547
Total/m²									264516

*Wi – maximum subsidence value; εs+ – maximum tensile deformation valve of buildings east-west direction; εs− – maximum compression deformation valve of buildings east-west direction; εt+ – maximum tensile deformation valve of buildings north-south direction; εt− – maximum compression deformation valve of buildings north-south direction;

4.2 *Ground movement and deformation prediction*

The design using the probability integral method for prediction of surface movement and deformation caused by mining is adopted.

The prediction and analysis of filling mining working condition of 4# coal fully mining +2# coal higher slice (2.8 m) +2# coal lower slice (2.7 m) is as shown in Table 4.

From the table, it shows that after 4# coal fully mining and 2# coal filling mining, within the scope of the village deformation, the maximum horizontal deformation value is +2.92/–3.04 (mm/m), the II-level damage area of the village is 264516 m² accounting for 33% of the village with a total area of 784617 m².

5 ANALYSIS OF ECONOMIC BENEFITS AND SOCIAL BENEFITS

5.1 *Economic benefits of filling mining*

In the mining area of Dashucun coal pillar, the recovery rate is calculated at 82%, 4# coal can be produced 1.427 million tons with caving mining method. Coal mining profit is calculated at 100 yuan per ton, then 4# coal total profit can be 142.7 million yuan; 2# coal can be produced 6.038 million tons with filling mining method, coal filling costs 49.17 yuan per ton, then coal filling profit is calculated at 50.83 yuan and 2# coal total profit can be 306.91 million yuan; After coal mining, the total profit of 4# and 2# coal can be 449.61 million yuan. To deduct village compensation fees of 44.61 million yuan, enterprise net profit can be 405 million yuan.

5.2 *Analysis of social benefits*

Paste-like filling mining with remarkable social benefits and environmental benefits has opened up an ideal way for mining under buildings, railways and water and green mining (Liu Zhijun 2010).

1. To protect natural environment. Paste-like filling mining can control surface subsidence effectively, realize mining without villages relocation, protect surface environment, and maintain the balance of groundwater ecosystem.
2. To improve the recovery rate of coal resources. Paste-like filling mining improves coal resources recovery rate significantly, reduces the loss and waste of mineral resources, extends the service life of the coalmine mining, increases employment opportunities and at the same

time, increases the total mining production of the whole mine.
3. To realize green mining. Paste-like filling technology not only considers the needs of the mining process, but also considers the social requirements of comprehensive utilization and disposal of mining wastes, the environmental protection and pollution reduction. The waste such as coal gangue and fly ash are used in the underground backfilling to realize mining with no waste and pollution.

6 CONCLUSION

1. Dashucun village coal pillar mining adopts the paste-like cemented filling process, and for 2# coal mining, slicing and filling method is selected, the higher slice mining thickness is 2.8 m and the lower slice mining thickness is 2.7 m. The designed filling capability of filling system is considered to be 150 m^3/h.
2. In the area of Dashucun coal pillar, after 4# coal was fully mined, 2# coal adopts filling mining method, 2# coal production can be 6.038 million tons with the profit of 306.91 million yuan. The total profit of 2# and 4# coal can be 449.61 million yuan, after deducting village compensation fees, the enterprise net profit will be about 405 million yuan.
3. Paste-like filling mining with remarkable social benefits and environmental benefits has opened up an ideal way for mining under buildings, railways and water and green mining, that is beneficial to protect the natural environment, improve the recovery rate of coal resources and realize green mining.

Study of rockbolts nondestructive detecting based on improved immune Danger Theory

Xiaoyun Sun & Yang Zhao
School of Electrical and Electronics Engineering, Shijiazhuang Tiedao University, Shijiazhuang, Hebei Province, China

Jiulong Cheng & Xiaoyun Sun
State Key Laboratory of Coal Resources and Safe Mining, China University of Mining and Technology (Beijing), Beijing, China

ABSTRACT: Owning to terrible environment and sensitive disturbance for rockbolts, it is important and necessary to detect rockbolts quality accurately. A nondestructive detecting method of rockbolts based on immune danger theory is proposed, using acoustic stress reflection technology, a series of danger and abnormal signals are exacted. So the defect type is detected by immune danger theory. Compared with the current artificial immunity algorithm, the result shows that the former diagnose accuracy is higher.

1 INTRODUCTION

Rockbolts as an important part of the support system was used in underground tunnels widely, as well as in slope reinforcement of surrounding rock and supporting. There are important parameters to evaluate the quality of the rockbolts, such as rockbolts length, Anchorage section length, free section length and constructive defects (Such as the imperfect location and grouting saturation in the rockbolts body). But rockbolts construction is concealed work. As the conventional method, pull-out and coring experiment are not only belong to destructive testing methods, but also are difficult to make effective detection. Existing non-destructive testing technology mainly includes electromagnetic method, sonic frequency stress wave method and ultrasonic method. The general information processing technology could not effectively test the quality of rockbolts, because it is difficult to distinguish the bottom reflected signal of rockbolts detection at present. Many scholars at home and abroad have been considerable research on nondestructive testing of rockbolts (Sun & Cheng 2008, Sun et al. 2012, He et al. 2004, Liu & Yue 2006, Xv 2002).

Most of the theory about the Artificial Immune System (AIS) were based on the self-nonself model which was introduced early. People think of that the organism could identify the "self" or "nonself" automatically and make immune response again "nonself". The theory has been widespread application in many fields such as pattern recognition, data processing, network security, optimization study and fault diagnosis (Mo & Zuo 2009). But the system needs identify and process all signal (antigen) which is different with "self" by the detector (antibody). A best complete detector set should be set up to reduce the missed detection probability of system. So the scale of the detector set would exponential increase follow the size of detector room (Zhou & Dasgupta 2007). Therefore, it leads to consume large amounts of resources and time in actual testing.

In 1944, Matzinger, a United States NIH immunology expert, proposed the immune-danger model theory (Matzinger 1994, Matzinger 2001). He considered that the key to specific immune response lies in danger signal rather than "nonself". Under the influence of different impulse force and impulse point, the audio reflected wave would be varying degrees fluctuate in rockbolts detecting. If abnormal signals are distributed at the edge of detectors detection space, the fluctuation would make some data point fall outside the detection space and omit. There must be some noise in the sampled signal. There are also residual even by the signal processing method. So it makes false alarm.

To address the problem, this danger theory for reference by the article, propose the immune danger theory algorithm to test rockbolts. The algorithm overcomes the limitations of the artificial immune system based on "self-nonself" pattern. It only need process the "danger" signal to complete

the rockbolts quality detection, rather than process all "nonself" signals. Reduce the omission and false alarm and enhance the speed and accuracy of rockbolts quality detection.

2 IMMUNE DANGER ALGORITHM

2.1 *Variable radius detector*

Immune algorithm is the detection about "self-nonself". It is a round area which was covered by each detector and without overlaping each other. There must be detecting vulnerability between adjacent detectors. In order to reduce the test loophole we can make the radius of detector as variable, and there is a maximum. It can fill the loophole between detectors and improve the fault coverage rate (Liu 2009).

2.2 *Detector cluster*

As the detector set were generated at random and even distributed, it could distinguish between "self" set and "nonslef" set only, but not the concrete types of "nonself". That is to say, it could only find the abnormal data.

The initial detector set was produced according to the self set, so the detectors were uneven distributed. The maximum detection radius has been defined r in order to make the detectors even distributed. If there are some overlapping areas between the new detector and any detector in the set, the new detector should be abandon until the detector is eligible.

2.3 *Affinity of antigen and antibody*

The known self set 'a' whose count is M and dimension is N in the system can be defined antibody. Its expression can be described as follows (Guo et al. 2012).

$$\mathrm{a} = \{V_{a1}, V_{a2}, \cdots, V_{aM}\} \tag{1}$$

Note:

$$V_{ai} = (V_{ai1}, V_{ai2}, \cdots, V_{aiN}), 0 \le V_{ai} \le 1, i = 1, 2, \cdots M$$

The known nonself set 'b' in the system whose count is M and dimension is N. we can define is antigen. Its expression can be described as follows.

$$\mathrm{b} = \{V_{b1}, V_{b2}, \cdots, V_{bM}\} \tag{2}$$

Note:

$$V_{bi} = (V_{bi1}, V_{bi2}, \cdots, V_{biN}), 0 \le V_{bi} \le 1, i = 1, 2, \cdots M$$

The expression of affinity 'u' between antibody and antigen can be described as follows.

$$u = 1/(1 + \sum_{i=1}^{M} \sqrt{\sum_{j=1}^{N} (V_{aij} - V_{bij})^2}) \tag{3}$$

Note:

$$0 \le V_{ai} \le 1, i = 1, 2, \cdots M, j = 1, 2, \cdots N$$

$$0 \le V_{bi} \le 1, i = 1, 2, \cdots M, j = 1, 2, \cdots N$$

.

We usually define the input data as antigen and defined the detectors as antibody in the immune system.

$$\mathrm{d} = \sqrt{\sum_{j=1}^{N} (V_{aij} - V_{bij})^2} \tag{4}$$

The letter d above is the Euclidean distance between set 'a' and set 'b'. The smaller the distance is, the bigger the affinity 'u' is.

2.4 *Danger detection and abnormal detection*

For the sampled signal, we extract the characteristic of the danger signal and then compare the characteristic value with the danger threshold. If the value is larger than the danger threshold, "danger = 1", otherwise "danger = 0".

Compare the affinity between antigen and each element in self set. If there is affinity which is larger than the given abnormal value, "abnormal = 0", otherwise "abnormal = 1".

Compare the affinity between antigen and each element in self set. If there is affinity which is larger than the given abnormal value, "abnormal = 0", otherwise "abnormal = 1".

Only if the danger signal and abnormal signal are both equal to 1, the immune response would take place and the fault type would be judged automatically.

2.5 *Rockbolts fault diagnosis algorithm based on immune danger theory*

The structure diagram of rockbolts quality diagnosis system based on immune danger theory is shown in Fig. 1.

- The detectors are produced according to self string. Then cluster the detectors according to nonself string and mark each kind of them. So we can get the mature detector set.
- Pretreat the input data and extract the characteristic vectors. Then it would become the antigen by normalizing them.

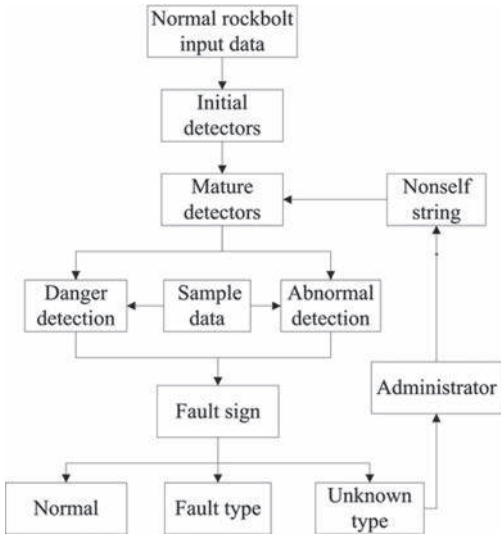

Figure 1. The rockbolts fault diagnosis system based on immune danger theory.

- Calculate the affinity between input antigen and every antibody.
- Compare each affinity with the given abnormal value. Send the abnormal signal which is "abnormal = 1" if the affinity is smaller than the value.
- Send the danger signal "danger = 1" if the danger characteristic value of antigen is larger than the danger value.
- If "danger = 1" and "abnormal = 1" are right, the immune response would be activated.
- We can compare all the sets which the antigen belongs to one by one to judge the type of antigen according to the cluster. Alarm the administrator and let him process the self and nonself sets if it is not in the type which it belongs to.

3 EXPERIMENT ANALYSIS

ANSYS-DYNA has been used to model and simulate for the different kinds of rockbolts in this experiment. The sampling frequency is 20 KHz. Simulate hammer knocking the head of rockbolts, and then get the acceleration waveform curves of the top rockbolts with the sensors at the top of rockbolts collecting the reflected wave. Including 12 groups normal data and 22 groups defects, long and short data. Figure 2–5, respectively, for normal, internal defects, long and short casting models.

3.1 *Data preprocessing*

According to the acceleration waveform curves of the top rockbolts, its vertical amplitude means

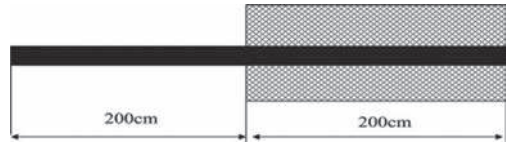

Figure 2. Normal rockbolts casting model diagram.

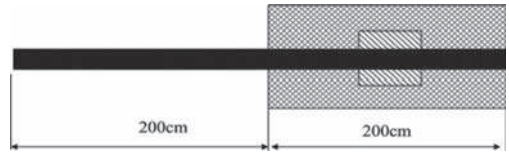

Figure 3. Internal defects rockbolts casting model diagram.

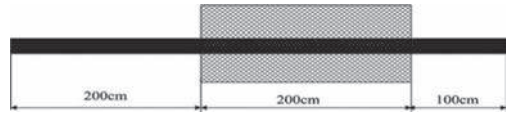

Figure 4. Long rockbolts casting model diagram.

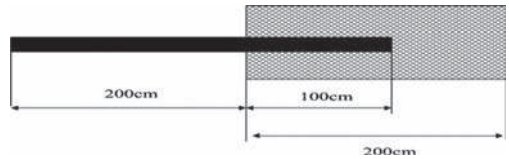

Figure 5. Short rockbolts casting model diagram.

reflected wave energy. The reflection points at the top and bottom of anchorage section could be found out. The data pretreatment includes 2 parts.

- Solve the amplitude of acceleration curves quadratic sum 'E' between the top and the bottom interface of anchorage part.

$$E = \sum y_i^2 \tag{5}$$

Make it normalized.

$$E^* = E/\max E \tag{6}$$

- Solve the maximum amplitude point in the anchorage part and make it normalized.

$$Y^* = Y/\max Y \tag{7}$$

Make up a two-dimensional normalized feature vector with two characteristic values E* and Y*.

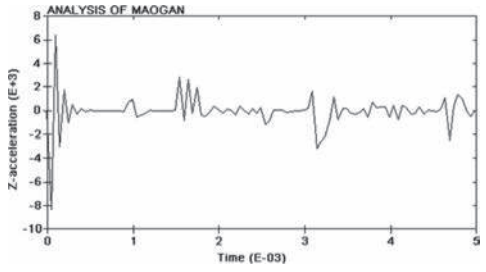

Figure 6. The acceleration waveform curves of the top normal rockbolts.

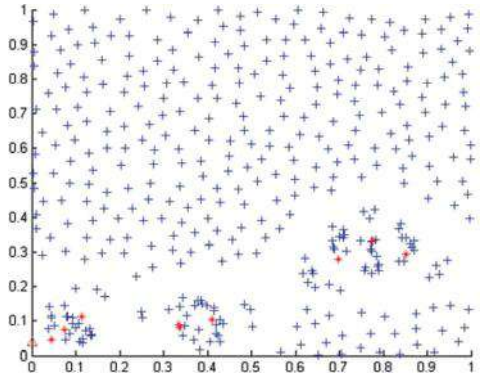

Figure 7. The distribution map of mature detector.

Then use it to research the condition of rockbolts anchorage quality.

3.2 *Numerical simulation and verification*

The acceleration waveform curves of the top rockbolts whose free section and anchorage section both are 2 m, as shown in Fig. 6. Then the feature vector could be got with the method above. Points A and B are the reflection points at the top and bottom of anchorage section.

According to formula (6) and (7), acquire the feature vector of known normal rockbolts and for testing rockbolts. Make the former as self set and the latter as nonself set. Execute the first step of algorithm, the initial detector set has produced with self and nonself sets and cluster them, as shown in Fig. 7. '+' stands for detector, '*' stands for nonself string and 'Δ' stands for self string. It achieved mark the type of rockbolts by cluster operations. The distance from detector to nonself string was more closely, but the detectors are uniform distribution in all the space if the distance is more than the given value.

The data of Table 1 and Table 2 is the experimental result by testing the simulation data of rockbolts.

They are using the detecting algorithm based on danger theory (DT) and traditional artificial

immune algorithm based on "self-nonself" model (SNS) respectively. The acceleration waveform curve could be got by modeling and simulating the rockbolts with the software ANSYS-DYNA. So simulation data of rockbolts could be got by sampling and pretreatment the curve.

It is obvious in the tables, the fault diagnosis rate of normal rockbolts is 91.67% and fault diagnosis rate of abnormal rockbolts is 90.91% with the detecting algorithm based on immune danger theory. The fault diagnosis rate of normal rockbolts is 83.33% and fault diagnosis rate of abnormal rockbolts is 86.36% with traditional artificial immune algorithm based on "self-nonself" model.

4 CONCLUSION

This article has presented a new fault diagnosis algorithm based on the danger theory of biological immunology. It judges the fault type of rockbolts through the synergy of danger signal and abnormal signal. It has overcome the limitation of artificial immune system model based on "self-nonself". The experimental results show that the method has higher detection validity and fault coverage than traditional artificial immune algorithm.

Experimental study on fireproofing performance of active explosion suppression system

Yong-Yu Wang, Jun-Feng Wang, Yu-Long Zhang, Jian-Ming Wu & Shuo Liu
College of Mining and Technology, Tai Yuan University of Technology, Taiyuan, P.R. China

ABSTRACT: Based on the theory of the system of flame retardant and active explosion suppression used in the South Africa HS mine, three different experiments were conducted to investigate the effects of HS system's explosion suppression. Experimental results show that HS system is of excellent practical effects and reliable safety performance. This system has the ability to cut off chain reactions on gas explosion propagation effectively in a very short time. so as to prevent gas combustion and control gas explosion successfully. Therefore, HS system has tremendous promoting values in China.

1 INTRODUCTION

The accidents of coal mine gas explosion have always been one of the main accidents in coal mines. By the statistics, more than 90% of the coal mines in our country are gaseous mines, nearly half of which belong to high gaseous mines. In order to reduce the mine gas disasters, based on the codes and specifications in our country the equipment and/or facilities, which are insulating and for suppressing explosion, are required to set up in the corresponding position of underworkings in coal mine, such as high gassy mines, coal and gas outburst mines, multi-seam mining mines, and mines easy to spontaneous combustion. Currently water barrier and rock dust barrier are mainly utilized to suppress explosion in mines of China, but these kinds of passive measures do not achieve the desired effectiveness due to ventilation evaporation, rock dust pollution and damp agglomeration (Wang Jun-feng et al. 2010).

The explosion suppression system used in the South Africa HS mine is an active explosion suppression system developed exclusively by Hans in South Africa. It could change traditional passive explosion suppression system to active explosion suppression system and timely block reaction chain of gas explosion effectively. This technology of explosion suppression has been at the international advanced level (Ma Li et al. 2010). In the previous work (Wang Jun-feng et al. 2010), the four basic parameters of this system, i.e., lag time of spraying, time for fogging, duration of effective fog and rate for spraying were systematically measured and calculated. These results shows that the system can effectively restrain the combustion and explosion of gas and dust in coal mine. In this paper, based on the theory of the explosion suppression of HS system, the basic function parameters of HS system were further measured according to the home and abroad regulations and standards (GB/T18154-2000, EN/1127-1, EN/14373). Meanwhile, the effect of active explosion suppression of HS explosion suppression system was further verified by combined with field-tested, data processing and theoretical analysis.

2 THEORY FOR THE HS SYSTEM

HS explosion suppression system is an active suppression system, which theory is shown in Fig. 1. When a methane or dust explosion occurs in the local areas of coal mine, the system can use its optical detector to monitor the accident point, and automatically transmits the signal to the central electronic controller in a few milliseconds. After the signal is checked, the controller will issue a instruction to open the high-pressure vessel, and the explosion suppression materials stored in the high-pressure container are released in a short period time, which enables to form a physical barrier to block extreme pressure and high temperature resulting from explosions. And then the fire could be extinguished simultaneously. Therefore, this system can cut down the scale of this disaster, and reduce the release of harmful gases in the end (Wang Jun-feng et al. 2010, Ma Li et al. 2010).

3 HS SYSTEM TEST FOR ACTIVE EXPLOSION SUPPRESSION AND FLAME RETARDANT

In order to study the HS mine system performance of active suppression and flame retardant, and

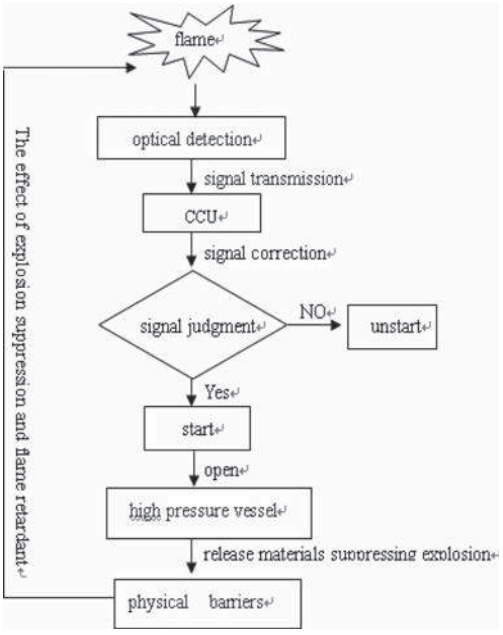

Figure 1. HS system theory for active explosion suppression and flame retardant.

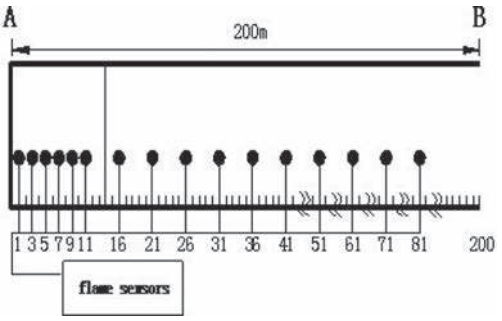

Figure 2. Appearance of testing gallery.

Figure 3. Explosion test without using CH4-2 system.

verify the effectiveness of the system, a group of pipeline tests about gas explosion suppression was conducted, which is similar to our previous studies (Wang Jun-feng et al. 2010), and the process is simply described here.

3.1 *Test procedures*

Comparative tests were carried out to check out the performance of HS active suppression explosion. A cylinder (i.d. 3 m, length 220 m) is formed the testing gallery. The schematic of the testing gallery is shown in Fig. 2, left side (A) of which is closed, the right (B) side of which is open; From side A, 16 flame speed sensors was arranged along the length, with setting one sensor every 2 meters from 1 m to 11 m, every 5 meters from 12 m to 41 m, and every 10 meters from 42 m to 81 m. HS system was equipped with high speed camera (Speed MS50 K), whose spectrum range is 400 nm–1000 nm with 1300000 pixels, and its shutter speeds are 1300 frames/s. A volume of 65 m3 air mixed gas with the 8.5 ± 0.5% (v%) concentration of CH4 was ignited by DDH-I type ignition device, which was installed in the 1.2 m distance from blind end and 1.35 m above testing gallery. At the same time the signals inside roadway were collected.

3.2 *Test results and analysis*

The first experiment was carried out without using the CH4-2 system. In the distance of 12 m from side A, plastic film was used to build an enclosed space, which was evenly filled with 45 m3 of mixed gas including CH4 and air. The high-speed camera was used to take photos of explosion phenomena in the exit of roadway and the system of collection and analyses was applied to analyse and record flame propagation speed passing by sensors when starting ignition device detonated mixed gas in the blind end. The experimental results were shown in Fig. 3 and Fig. 4.

The moment of detonating the mixed gas in the testing gallery without CH4-2 system is shown in Fig. 3. A violent explosion was occurred, which causes the temperature to raise suddenly, generating a large amount of harmful gases including CO, and huge disruptions in the end. From the continuous curve of flame propagation velocity in Fig. 4, it can been seen that the flame propagation speed got faster with the increase of roadway distance and it maintained a great speed within a certain distance in the semi-closed testing gallery. The flame propagation speed was fitted and the reuslt is shown in Fig. 4. It can been see that the fitting curve fits well as a whole in addition to some individual points, and the relationship can be described by the following equation: $y = -4E\text{-}06x^5 + 0.0006x^4 - 0.0303x^3 + 0.2787x^2 + 10.889x - 21.266$. The fitting curve

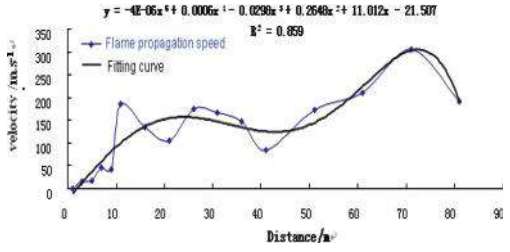

Figure 4. Explosion flame propagation speed without using CH4-2 system.

shows that within a certain distance away from the shot point, the flame propagation speed raised with the increase of the roadway distance and then it began to decrease when it reached the maximum distance at about 72 m from the semi-closed testing gallery. The reason for this trend is that with the combined effect of precursory shock waves and flame front produced by the initial explosion in the explosions, the flame area of combustible gases will be increased and stretched, and the propagation speed of flame wave will be increased continuously, and then reached the peak velocity in the end. At the last stage, due to the reduction of methane involved in the reaction per unit time, the energy generated by the combustion was not sufficient to supply the energy dissipation of shock wave spreading forward, the flame propagation speed decreased continually (Zhang Xiu-hua & Wu Yan-yan 2012, Wang Jun-feng et al. 2011).

In test 2, one CH4-2 machine was introduced into the test, which was set 5 m distance from blind end of testing gallery to check its positive effect of explosion suppression. In the distance of 12 m from blind end, plastic film was used to build an enclosed space, which was evenly filled with 65 m3 of mixed gas including CH_4 and air. Besides, some coal dusts with high explosibility were spread evenly in the 14 m distance from plastic film to demonstrate the explosion suppression effect of CH4–2 machine. A high-speed camera was used to take photos of explosion phenomena in the exit of roadway and a system of collection and analyse was applied to analyse and record the flame propagation passing speed by sensors when a starting ignition device detonated the mixed gas in the blind end. The experimental results are shown in Fig. 5 and Fig. 6.

Compared with Fig. 3 and Fig. 5, it can be found that the smoke produced by explosion was decreased rapidly and the explosive intensity was weakened obviously when one CH4-2 machine was set in the testing roadway. The test result show that its effect of explosion suppression was good. It also can been see from Fig. 6 that the no signal was detected by the sensors outside the 7 m distance

Figure 5. Explosion test with using one CH4-2 machine.

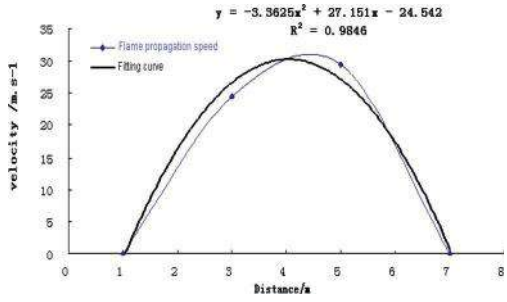

Figure 6. Explosion flame propagation speed with using one CH4-2 machine.

from blind end of testing gallery, which indicates that the explosive flame was controlled absolutely. The explosion flame propagation speed was also fitted, which can be expressed by: $y = -3.3625x^2 + 27.151x - 24.542$. These results show that the flame travel speed of gas explosion was decreased rapidly and then reduced to 0 when the flame propagated to 4 m distance from blind end in the testing gallery because of the flame retardant of CH4-2 machine. Besides, only a small quantity of coal dust was blown out according to analyzing the pictures taken by high-speed camera, which shows that the energy of gas explosion was weakened and its travel speed was decreased and the explosive blast was controlled. Experimental results showed that explosion phenomena was controlled indeed when one CH4-2 machine was set in the testing gallery. As a result, the gas explosion was controlled successfully and the expected effect of explosion suppression and flame retardant was achieved.

To take the further research on the effect of explosion suppression of HS machine, the test 3 was carried out. Two CH4-2 machines were set along the longitudinal of roadway to detect the performance of explosion suppression. One CH4-2 machine was set in the 7 m distance from blind end of testing gallery, while the other was set in the 12 m distance from blind end of testing gallery. In addition, plastic film was used to build an enclosed space in the distance of 12 m from blind end, which was evenly filled with 65 m^3 of mixed gas containing CH_4 and air. Meanwhile,

some explosive coal dusts were evenly spread in the 14 m distance from plastic film to demonstrate the effect of explosion suppression. The high-speed camera was used to take photos of explosion phenomena in the exit of roadway and the system of collection and analyses was applied to analyse and record flame propagation passing speed by sensors when detonating mixed gas was started with a ignition device. The experimental results are shown in Fig. 7 and Fig. 8.

Fig.7 shows the effect of explosion suppression when setting two CH4-2 machines in the testing gallery. Compared with Fig. 3 and Fig. 5, it can be seen that the explosion suppression of two CH4-2 machines performed well, which can be proved by the smoke produced by explosion at the exit of testing gallery was decreased obviously and the explosive intensity is weakened sharply. It also found that the machine set in the 7 m distance from blind end while the other one set at 12 m distance from blind end did not start, and the coal dusts were hardly blown out at the exit of testing gallery, which makes it clear that the spread of explosive flame was stopped at 10 m in the front of the second CH4-2 machine whose the farthest sensing distance is 10 m and it did not start because it did not induct enough signals. The test demonstrates that CH4-2 machine is able to suppress gas explosion absolutely under its normal work. The fitting result is shown in Fig. 8, which is similar to Fig. 4. It can be seen that the flame produced by explosion in the testing gallery was controlled in the 7 m distance from blind end because of flame retardance and explosion suppression of the first machine. Then the flame propagation speed was slowed down quickly and was reduced to 0 before it got to the second machine (in the 12 m distance from blind end), which demonstrates the machine worked well obviously. From the result of test 3, this conclusion can be found that the CH4-2 machine can form explosion suppression barriers with special flame retardant materials and block reaction chain of gas explosion effectively in a remarkably short period of time, and then nip possible gas accident in the bud.

Figure 7. Explosion test with using two CH4-2 machines.

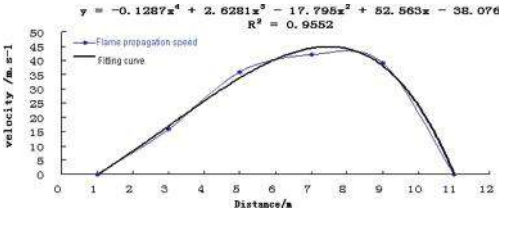

Figure 8. Explosion flame propagation speed with using two CH4-2 machines.

4 CONCLUSION

The South Africa's HS mine suppression system working principle is as follows: it detects and analyses mashgas (coal dust) explosion signal under mining depend on its optical detector; then it completes superspeed behavior of flame retardance and explosion suppression with the electronic controller; it replaces the traditional passive explosion suppression system with a active explosion suppression system. Through groups of experiments with the function of HS mine suppression system, it has been found that HS system indeed has a good practical effect and a reliable safety performance. This system can save workers lives and property as much as possible by blocking reaction chain of gas explosion effectively in a remarkably short period of time and realize the goal of flame retardance and explosion suppression. The South Africa's HS mine suppression system, which is an advanced technique and has very strong vitality, fills the void in terms of active explosion suppression in China. Therefore, it shows great promoting values and wide ranges of potential applications in China.

ABSTRACT: A commercial software package AutoReaGas, was used to carry out the numerical investigation for the distribution difference of shockwave from methane-air explosion in coal laneways under different concentrations of methane. The study verifies that the strongest shockwave is produced under the optimum concentration. The higher the concentration in premixed area, the larger the increasing area of shockwave overpressure, and the larger the distance between the location of shockwave overpressure maximum and the ignition in whole explosion field. The reason is that the propagation of the shockwave promotes the flow and diffusion of the unburned gaseous mixture in front of flame. A change of the methane-air mixing state and the premixed area gives rise to the distribution difference of shockwave on time and space.

1 INTRODUCTION

Gas explosion is one of the main types of accidents in coal mining. Gas explosion is a kind of nonpoint explosion. It is generally deflagration, but it can also reach detonation under specific conditions. There are many researches on the shock wave disasters in gas explosion. Gas explosion is volume explosion, and the disaster effects are greatly influenced by external factors, resulting that the explosion shock wave related researches are mainly focused on the time and space distribution of shock wave intensity, influence factors on shock wave propagation, the damage criterion of shock wave and the disaster effects on human body. Ibrahim (2001) and Valeria (2009) studied the influence of obstacles in roadway on the explosion using experimental and large eddy simulation methods. They pointed out that bigger section blocking rate would bring higher shock wave peak overpressure and shorter time of arrival. Lin et al (2007) conducted gas explosion experiments in a pipe (80 mm × 80 mm in section) with some spiral metal ring inside. They found that the flame speed got higher with the increase of the height of ring. Ye et al (2005) studied the inhibitory effect of water spray on the pipe gas explosion by experiments, and found that the inhibitory effect is proportional to the spray density and length. Jia (2007) and Jing (2008) summarized the change law of the overpressure when shock waves ran through the discontinuity section of the laneway by the means of theoretical analysis.

The characteristics of gas have significant influence on the disaster effects in gas explosion and may complicate the disaster. For example, the peak overpressure of shock wave gets higher as the premixed area increases, and the attenuation of shock wave along the axis gets more slowly (Xu, J.D. & Xu, S.L. 2004). Any flammable gas has its corresponding explosion limit. The explosion limit of methane is about 4.6%−14.3% (Zhao, H.Y. 1996). Outside the range, even a strong ignition source cannot stimulate the explosion. The explosion limits of gas can be influenced by many factors, such as initial temperature, initial pressure, etc. and also it is directly related to the environment and the determination method. As to the flammable gas cloud within the scope of the explosion limit, the explosion parameters display a marked difference when concentrations vary. The optimal concentration often leads to the highest explosion parameters. For instance, the constant volume explosion overpressure of methane/air mixture at a concentration of 10.1% can reach as high as 0.86 MPa, and the highest temperature can reach 2340 K (Zhao, H.Y. 1996).

Obviously, this concentration is slightly higher than the stoichiometric concentration (9.5%) of methane. Therefore, study of the effects of gas concentration on the gas explosion in laneways is of great significance for the understanding gas explosion mechanism and accident prevention. In this work, the different distributions of shock wave in underground gas explosion at different concentrations are researched by CFD code AutoReaGas. The physical mechanism of how gas concentration affects the shock wave disaster is revealed.

2 NUMERICAL METHOD

In this article, the gas explosion process meets mass, momentum, energy and chemical components conservation equations. The k-ε turbulence model is used to model the turbulence which is the key factors in the gas explosion, and the single-step chemical reaction is used to describe the reaction process of gas explosion. AutoReaGas uses following model (AutoReaGas™ Interactive Software Theory Manual. 2002 & AutoReaGas™ Reactive Gas Dynamics and Blast Analysis software User Manual Version 3.1. 2002) to describe the turbulent burning velocity:

$$S_t = 1.8u'^{0.412} \cdot L_t^{0.196} \cdot S_l^{0.784} \cdot \nu^{-0.196} \quad (1)$$

Where, u' is turbulence intensity, L_t the characteristic length scales, S_l the laminar burning velocity, S_t the turbulent burning velocity, and ν is kinematic viscosity.

The coupling problem between the pressure and velocity in transient flow field is numerically solved by the finite volume discrete methods and the improved SIMPLEC algorithm. Rectangular grids are used in the discretization in space. Because of the limitation of computing power, the effect of small scale physical objects on explosion flow field is calculated by sub-grid technique in AutoReaGas (AutoReaGas™ Interactive Software Theory Manual. 2002, AutoReaGas™ Reactive Gas Dynamics and Blast Analysis Software User Manual Version 3.1. 2002, Maremonti, M., Russo, G., Maremonti, E. & Tufano, V. 1999, Tufano, V., Maremonti, M., Salzano, E. & Russo, G. 1988, Salzano, E., Marra, F.S., Russo, G., Lee, J.H.S. 2002 & Bretislav, J., Petr, S., Jan, H.& Lukas, V. 2006).

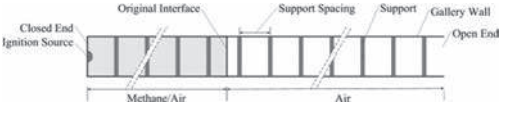
AutoReaGas is mainly used to simulate gas explosion and its shock effect. It is specifically designed for congestion and restrictions (AutoRea -Gas™ Interactive Software Theory Manual. 2002 & AutoReaGas™ Reactive Gas Dynamics and Blast Analysis software User Manual Version 3.1. 2002). The reliability of AutoReaGas in the field of gas explosion has been verified. The reliability of this software in the numerical simulation on gas explosion have been reported in literature (AutoRea -Gas™ Interactive Software Theory Manual. 2002, AutoReaGas™ Reactive Gas Dynamics and Blast Analysis software User Manual Version 3.1. 2002, Maremonti, M., Russo, G., Maremonti, E. & Tufano, V. 1999, Tufano, V., Maremonti, M., Salzano, E. & Russo, G. 1988, Salzano, E., Marra, F.S., Russo, G., Lee, J.H.S. 2002 & Bretislav, J., Petr, S., Jan, H.& Lukas, V. 2006).

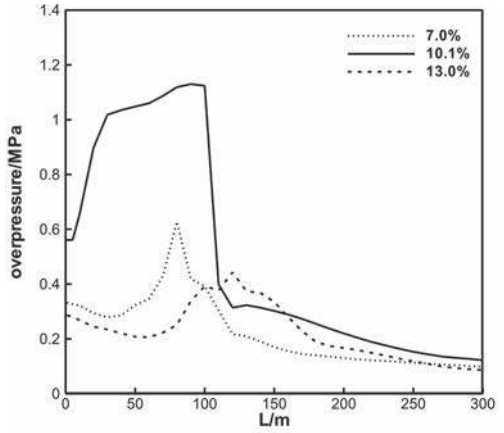
3 NUMERICAL PROCEDURE

The calculation model is a 1000 m straight laneway with a section area of 6 m^2, as shown fig. 1. One end is closed and the other is open. According to the grid feature, the cross section is simplified to a square shape, 2.45 m × 2.45 m. A weak hemispherical ignition source is set near the closed end. At initial moment, the gas is premixed and perfectly still. Kindracki (2007) found that the maximum explosion parameters are obtained when methane concentration in air is higher than 9.5%. So the concentration of 10.1% (Zhao, H.Y. 1996) is chosen in this study. The premixed methane/air mixture is 100 m long. The support system is simplified to rectangular pillars with a section size of 0.1 m × 0.1 m and the space is 1 m. Three different methane concentrations, 7.0%, 10.1% and 13.0% are set for this simulation. The grid size is 0.49 m × 0.49 m in radial direction and 0.50 m in axial direction. The total number of grid and node are 50000 and 72036 respectively.

4 RESULTS AND ANALYSIS

Monitoring points are located in center of the cross section of the roadway. Profiles of peak overpressures along with the axial distance for different gas concentration are shown in Fig. 2. Firstly, in the whole explosion field, the shock wave overpressure under the concentration of 10.1 (1.13 MPa) is higher than that under the concentration of 7.0% (0.63 MPa) and 13.0% (0.44 MPa) which confirmed that the maximum explosion parameters can be obtained at the optimum concentration, while the explosion parameters will decrease when the concentration goes higher or lower than the optimum concentration.





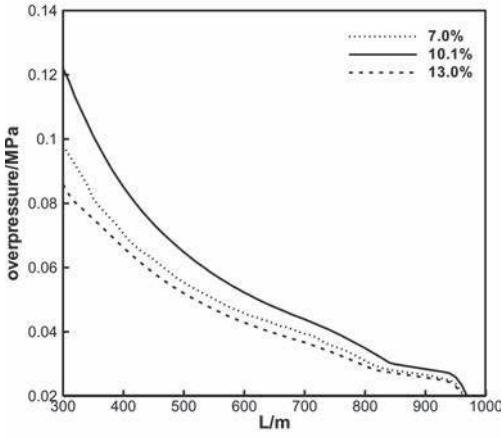


Figure 1. Top view of calculation model.

(a) L<300 m

(b) L>300 m

Figure 2. Peak overpressure vs. axial distance under different concentrations.

In figure 2, the peak overpressures along the axial distance for all three kinds of concentrations firstly increase rapidly, and then turn gradually attenuated. If the overpressure rising area is defined as shock waves near field and the attenuation area as far field, the higher the gas concentration of premixed area is, the larger the shock wave near field range gets. Near field ranges for these three kinds of concentration are 80 m, 100 m and 120 m respectively. It also shows that the peak overpressure in the whole flow field gets farther from the explosion source for higher gas concentration. In addition, according to figure 2(b), the peak overpressure for the optimum concentration is always the highest at the same axial location.

The gas concentration of premixed area also influences the spread of flames. According to the calculation results, the lengths of flame area under these three concentrations (7.0%, 10.1%, and 13.0%) are 110 m, 250 m and 280 m respectively. It suggests that when the gas concentration of premixed area is lower than the optimal concentration and higher than the lower explosion limit, the flame area range is close to the premixed area; when at the optimum concentration, the flame area is longer than the premixed area length; When at a concentration higher than the optimum concentration and lower than the higher explosion limit, the flame area is longer than the premixed area length and also a little longer than the flame area length corresponding to the optimum concentration.

According to the physical mechanism of gas explosion, when the concentration of premixed gas mixture is higher than the optimum concentration and lower than the higher explosion limit, the shock wave overpressure inside the premixed area could not reach the highest value. As the shock wave propagates along the laneway axis, a large amount of unburned gas diffuses and expands forward in the same direction, and reaches the optimum concentration at certain location outside the premixed area, and then the highest overpressure turns up. When the concentration of premixed gas mixture is lower than the optimum concentration and higher than the lower explosion limit, the unburned gas diffuses forward as the shock wave propagates, and the highest overpressure appear at a location after which the gas concentration gets lower. Thus higher overpressure will never appear any more.

5 CONCLUSION

The shock wave diffusion under different premixed gas concentrations are researched by numerical method. It is confirmed that the explosion parameters is the highest under the optimum concentration, while at a concentration higher or lower than the optimum concentration, the explosion parameters will go down. When gas concentration gets higher, the range of overpressure rising area gets larger, and the maximum overpressure in the whole flow field appears farther from the explosion source. This is because that the spread of shock wave make the unburned gas ahead of the flames flow and diffuse, which will change the methane/air mixing state and the range of mixed area and result in the distribution difference of shock wave and flame in time and space. The difference of explosion disaster effect and the diffusion mechanism of unburned gas under different gas concentrations are the based study references

for the accident investigation and prevention, the transition from gas explosion to combustion and the conversion mechanism between explosion and fire hazard.

School of Safty Engineering, North China Institute of Science and Technology, Beijing, China

ABSTRACT: In order to predict the relative emission volume of mine gas, a model called grey system theory is built by using the relaxative operator theory. To apply this model to forecast the emission volume of mine gas, we create the grey theory depending on the emission volume in coal mine, and then to forecast the grey system of coal mine. It is shown that the grey system model has the first-degree precision by comparing the degrees of precision.

1 INTRODUCTION

With the development of the economy of China, the demand of coal become in a higher tension gradually. During this period, the serious accidents of coalmine consistently happen in the state. Among these accidents, the accidents caused by the explosion of gas are in a high proportion, and it directly leads to the loss of the economy and human's safety. Hence, one measure to prevent such accidents is to accurately forecast the emission of coalmine. There are many geological factors affecting the emission of gas. The nonlinear relation among these factors is very complicated and uncontrolled. So, it's difficult to forecast the volume of emission of gas from coal mine.

The grey system is a totally new traverse science invented by China's notable scholar Prof. Julong Deng at 1982. It's mainly to research the uncertain system which only includes small sample or limited information. By creating, developing and extracting the effective information from the known part, the action of a system can be correctly recognized and effectively controlled. In last 20 years, the Grey System was not only developing in the theoretical field, but in the field of natural science and social science it brought about a series of breakthroughs.

In the paper "The application of the grey system to forecast the emission volume of gas from coal mine" published in the academic journal of coal, No. 5, I notice that the original value of 2003 is 2.675 while the forecasted value is 5.135, so the relative error reaches to 91.9% (Wu A. et al. 2005). Meanwhile, in the precision test, the values of C and P are also improper. Conclusively, the precision is low and couldn't be utilized. However, by the relaxative operator theory to improve, the result is in a high precision and meets the requirement of the first degree precision.

2 THE THEORY AND ANALYSIS OF THE GM(1, 1) MODEL

In the application of Grey System Theory to forecast the emission volume of gas from coal mine, we usually select a grey system theoretical differential equation model called GM(1, 1) which includes a first-order variable. The forecasting process can be split to three steps: grey generation, parameter calculation and precision test.

2.1 *Grey generation*

We define the original series as $X^{(0)} = (x^{(0)}(1), x^{(0)}(2), \ldots, x^{(0)}(n))$, and n is the length of the series. By the process of accumulating and generating, we get the series $X^{(1)} = (x^{(1)}(1), x^{(1)}(2), \ldots, x^{(1)}(n))$, and

$$x_k^{(1)} = \sum_{j=1}^{k} x_j^{(0)}$$

Based on the generated series, we build the grey generation model

$$\frac{dx^{(1)}}{dt} + ax^{(1)} = b \tag{1}$$

(1) is the grey differential equation, noted as *GM* (1, 1), and a, b are the parameters to be identified.

2.2 *Parameters calculation*

The parameters in (1) is obtained by the Least Squares Method $\begin{pmatrix} a \\ b \end{pmatrix} = (B^T B)^{-1} B^T y_n$, and

$$B = \begin{pmatrix} -(x_1^{(1)} + x_2^{(1)})/2 & 1 \\ -(x_2^{(1)} + x_3^{(1)})/2 & 1 \\ \vdots & \vdots \\ -(x_{n-1}^{(1)} + x_n^{(1)})/2 & 1 \end{pmatrix}, \quad y_n = \left(x_2^{(1)}, x_3^{(1)}, \ldots, x_n^{(1)}\right) \tag{2}$$

The discrete time responding variable $\hat{x}_{k+1}^{(1)}$ is determined by the following equation

$$\hat{x}_{k+1}^{(1)} = \left(x_1^{(1)} - \frac{b}{a}\right) e^{-ak} + \frac{b}{a} \tag{3}$$

We then reduce $\hat{x}_{k+1}^{(1)}$ by accumulating, and the estimation of the original data are

$$\hat{x}_{k+1}^{(0)}, \quad \hat{x}_{k+1}^{(0)} = \hat{x}_{k+1}^{(1)} - \hat{x}_k^{(1)} \tag{4}$$

2.3 *Precision test*

We define the original series as $X^{(0)} = (x^{(0)}(1), x^{(0)}(2), \ldots, x^{(0)}(n))$, The simulating series of that model is

$$\hat{X}^{(0)} = \left(\hat{x}^{(0)}(1), \hat{x}^{(0)}(2), \ldots, \hat{x}^{(0)}(n)\right)$$

The residues is

$$\varepsilon^{(0)} = \left(\varepsilon^{(0)}(1), \varepsilon^{(0)}(2), \ldots, \varepsilon^{(0)}(n)\right) = \left(x^{(0)}(1) - \hat{x}^{(0)}(1), \ldots, x^{(0)}(n) - \hat{x}^{(0)}(n)\right)$$

The relative error series is

$$\Delta = \left(\left|\frac{\varepsilon(1)}{x^{(0)}(1)}\right|, \left|\frac{\varepsilon(2)}{x^{(0)}(2)}\right|, \ldots, \left|\frac{\varepsilon(n)}{x^{(0)}(n)}\right|\right) = \{\Delta_k\}_1^n$$

We define $\bar{\Delta} = \frac{1}{n}\Sigma_{k=1}^{n}\Delta_k$ as the average simulating relative error, $1 - \bar{\Delta}$ as average relative precision. When $\bar{\Delta} < \alpha$ and $\Delta_n < \alpha$ (the given $\alpha > 0$), the model is called residuals qualified model.

Defining ε as the absolute relevant degree of $X^{(0)}$ and $\hat{X}^{(0)}$, if $\varepsilon_0 > 0$ is given and $\varepsilon > \varepsilon_0$, we call the model as the relevant degree qualified model.

Defining

$$\bar{x} = \frac{1}{n}\sum_{k=1}^{n} x^{(0)}(k), S_1^2 = \frac{1}{n}\sum_{k=1}^{n}(x^{(0)}(k) - \bar{x})^2,$$

$$\bar{\varepsilon} = \frac{1}{n}\sum_{k=1}^{n}\varepsilon(k), S_2^2 = \frac{1}{n}\sum_{k=1}^{n}(\varepsilon(k) - \bar{\varepsilon})^2$$

Table 1. The degrees of the precision test.

Index Precision Critical value Degree	Relative error α	Relevant degree ε_0	Ave Variance rate c_0	Small Prob errot P_0
1st degree	0.01	0.90	0.35	0.95
2nd degree	0.05	0.80	0.50	0.80
3rd degree	0.10	0.70	0.65	0.70
4th degree	0.20	0.60	0.80	0.60

C = S2/S1 is the average variance ratio, and when C0 > 0 and C < C0, we call the model as the average variance ratio qualified model $P = P(|\varepsilon(k) - \bar{\varepsilon}| < 0.6745 \cdot S_1)$ is called small error probability. When $P_0 > 0$ and $P > P_0$, we call the model as small error probability qualified model.

The four definitions above are the methods to test the model. They all judge the precision by criticizing the residues. To give values to *a, ε, C, P* is to determine the degree of simulating the precision. The commonly used precision degrees can be seen in Table 1.

Generally, the commonly used index is the relative error test.

3 THE RELAXATIVE THEORY

In the grey theory, before modeling, we usually take a relaxative operator to the original series according to the qualitative analysis. It will result to that the disturbance to the series will be weakened, and also result to a desirable effect.

We call an operator as the relaxative operator when it meets three axioms below (Si F. et al. 1999).

Axiom 1 (fixed point axiom): Defining X as the data series of systematic action, D is the series operator, namely XD = (x(1)d, x(2)d, …,x(n)d), so D meets that x(n)d = x(n).

Axiom 2 (information fully used axiom): The data x(k)d, (k = 1, 2…, n) in the data series of systematic action should react with the operator in the whole process.

Axiom 3 (Analysis axiom):Any x(k)d, (k = 1, 2…, n) can be expressed by elemental formula including x(1), x(2), x(3).

We regard the operator meeting the three axioms as the relaxative operator. If the rate or amplitude of the relaxative series is weaker w-hen compared to the original series X, the relaxative operator will be called weakened operator. Otherwise, the relaxative operator will be called strengthened operator. The operator below is a commonly used weakened operator.

We define the original series as X = (x(1), x(2), …, x(n)), and make XD = (x(1)d, x(2)d, …,x(n)d) and

$$x(k)d = \frac{1}{n-k+1} \times \left[x(k)+x(k+1)+\cdots+x(n)\right]; k = 1,2,\ldots,n$$

When X is an increasing series, decreasing or fluctuating series, D is a weakened operator.

$$XD^2 = XDD = (x(1)d^2, x(2)d^2, \cdots, x(n)d^2)$$

And

$$x(k)d^2 = \frac{1}{n-k+1}\left[x(k)d + x(k+1)d + \cdots + x(n)d\right]; \quad k = 1,2,\ldots,n$$

When D^2 is an increasing series, decreasing or fluctuating series, D^2 is a second-order weakened operator.

4 FORECASTING THE EMISSION VOLUME OF GAS FROM COAL MINE BY RELAXATIVE OPERATOR

The emission volume of gas from coal mine is influenced by many factors, the relationship among which is very complicated. So it's obviously a gre-y system. The data of the emission volume of gas in last 10 years at a coal mine are shown in table 2.

4.1 *The original data by a weakened operator weak the influence of the disturbance to the sy-stematic action*

The original series is

$$X^{(0)} = \left(x^{(0)}(1), x^{(0)}(2), x^{(0)}(3), \ldots, x^{(0)}(10)\right) = \left(2.685, 4.095, 2.725, \ldots, 3.053\right)$$

To exert a weakened operator D above mentioned on $X^{(0)}$, we get

$X^{(0)}D$ = (3.7276, 3.8434, 3.8120, 3.9673, 3.8452, 4.0468, 4.0028, 3.7093, 2.864, 3.053)

$X^{(0)}D^2$ = (3.6871, 3.6826, 3.6626, 3.6412, 3.5869, 3.5352, 3.4072, 3.2088, 2.9585, 3.053)

Defining

X = (3.6871, 3.6826, 3.6626, 3.6412, 3.5869, 3.5352, 3.4072, 3.2088, 2.9585, 3.053)

X's 1-AGO is

$X^{(1)}$ = ($x^{(1)}(1)$, $x^{(1)}(2)$, $x^{(1)}(3)$, …, $x^{(1)}(10)$)
= (3.6871, 7.3697, 11.0323, 14.6735, 18.2604, 21.7956, 25.2028, 28.4116, 31.3701, 34.4231)

4.2 *Building the systematic model of forecasting the emission volume of gas*

We get $X^{(1)}$ by accumulating, the built data matrix B, y_N is

$$B = \begin{pmatrix} -5.284 & 1 \\ -9.2210 & 1 \\ \vdots & \vdots \\ -32.8966 & 1 \end{pmatrix},$$

$$y_N = \left(7.3697, 11.0323, 14.6735, \ldots, 34.4231\right)$$

From (3), we get

$$\begin{pmatrix} a \\ b \end{pmatrix} = \begin{pmatrix} 0.0272 \\ 3.9514 \end{pmatrix}, \quad \frac{b}{a} = 145.272$$

The forecasting model is

$$\hat{x}_{k+1}^{(1)} = -141.585e^{-0.0272k} + 145.272$$

The results are in table 3 in next page.

4.3 *Precision test*

By calculations,

$$\bar{\varepsilon} = -0.00075, \bar{x} = 3.4423, \Delta = 0.0208,$$
$$\Delta_n = 0.0011, S_1 = 0.2602, S_2 = 0.0906$$

$$C = \frac{S_2}{S_1} = 0.3482 < .035, 0.6745 \cdot S_1 = 0.1755,$$
$$P = P(|\varepsilon(k) - \bar{\varepsilon}| < 0.6745 \cdot S_1) = 0.90$$

Table 2. Statistic of gas relative emission of 4th ward of some coal mine.

Year	1994	1995	1996	1997	1998	1999	2000	2001	2002	2003
Elative emission volume of gas /$m^3 \cdot (t \cdot d)^{-1}$	2.685	4.095	2.725	4.700	2.837	4.223	4.388	5.400	2.675	3.053

Table 3. Statistic data analysis of gas relative emission.

Year	Rank	x	$x^{(1)}$	Grey forecasting $\hat{x}^{(1)}$	Grey forecasting $\hat{x}$	$\varepsilon^{(0)}$
1994	1	3.6871	3.6871	3.6871	3.6871	0
1995	2	3.6826	7.3697	7.4862	3.7991	–0.1165
1996	3	3.6626	11.0323	11.1835	3.6973	–0.0347
1997	4	3.6412	14.6735	14.7815	3.5980	0.0432
1998	5	3.5869	18.2604	18.2830	3.5015	0.0854
1999	6	3.5352	21.7956	21.6906	3.4076	0.1276
2000	7	3.4072	25.2028	25.0067	3.3161	0.0911
2001	8	3.2088	28.4116	28.2338	3.2271	–0.0183
2002	9	2.9585	31.3701	31.3743	3.1405	–0.182
2003	10	3.053	34.4231	34.4306	3.0563	–0.0033

$$|s| = \left| \sum_{k=2}^{9} (x(k) - x(1)) + \frac{1}{2}(x(10) - x(1)) \right| = 2.1314$$

$$|\hat{s}| = \left| \sum_{k=2}^{9} (\hat{x}(k) - \hat{x}(1)) + \frac{1}{2}(\hat{x}(10) - \hat{x}(1)) \right| = 2.1250$$

$$|\hat{s} - s| = \left| \sum_{k=2}^{9} [(x(k) - x(1)) - (\hat{x}(k) - \hat{x}(1))] + \frac{1}{2}(x(10) - x(1)) - (\hat{x}(10) - \hat{x}(1)) \right| = 0.0064$$

$$\varepsilon = \frac{1 + |s| + |\hat{s}|}{1 + |s| + |\hat{s}| + |\hat{s} - s|} = \frac{5.2564}{5.2564 + 0.0064} = 0.9988 > 0.90$$

From the relative error test to see, the precision is close to the first degree; From the average variance test to see, the precision is in the first degree. From the small probability error test to see, the precision is close to the first degree; From the grey absolute relevant degree to see, the precision is in the first degree.

5 CONCLUSION

As we use the relaxative operator theory, it greatly reduces the influence of the disturbance on the data series of systematic actions. So, the forecasting effect above is more accurate than the original paper.

Outburst prevention technology and effects of hydraulic flushing with effects of pressure relief and increasing permeability

Wei Meng & Bo Li
College of Safety Science and Engineering, Henan Polytechnic University, Jiaozuo, Henan, China

ABSTRACT: The paper analyzed the advantages and disadvantages of hydraulic outburst prevention and expatiated on the validity of hydraulic flushing technique eliminating working face with outburst hazard. Studies have shown that high pressure water jet of hydraulic flushing technique could break coal body, change stress state of coal, increase preexisting cracks and produce more cracks improving permeability coefficient.

1 INTRODUCTION

Low air permeability coal seam has account for more than 95% of coal seams mined by the high mines and outburst mines, permeability coefficient in coal seam is just 10–3~10–4 mD thus it dreamed big to gas drainage and drainage rate is low. (Yu 1992, Wang 2005, Qin et al. 2008).

Mining protective layer and pre-pumping coal gas could release the crustal stress and gas potential in coal seam and change the properties of the coal itself which lead to eliminate outburst hazard in coal seam. Yet utilizing pressure relief antireflection strengthening pumping discharge is the most significant mean to eliminate outburst in single permeability coal seam which outburst seriously. Waterpower, mechanical force and bursting force are included in the dynamic for antireflection of pressure relief, the disadvantages of mechanical force and bursting force are listed as follows: operating process is difficult, range of pressure relief is limited and that is easy to produce sparks. Outburst prevention measures such as hydraulic extrusion, hydraulic cutting and hydraulic flushing achieved better application effect via experiments. However hydraulic extrusion and hydraulic cutting conducted in front of heading face or working face which belong to measures for eliminating outburst hazard partly, it induced outburst and cannot guarantee the safety in process that achieve little effect on advance eliminating outburst in region.

Hydraulic flushing utilizing rock roadway as safety barrier, adopt high pressure water jet to break up coal and rush out part coal and gas which aroused stress of coal and rock mass around drill decreased, pressure relief and strengthen drainage effective, for the sake of improving quantity of drainage, reducing measures of quantities, shortening the time of measures and eliminating outburst hazard in working face safely and rapidly. (Yu & Wang 2000, Lin & Cui 1992, Li 2006, Yao et al. 1993, Gas group of china mining college 1979) Not eliminate the hazard as jet orifice and outburst bring from drilling in coal roadway, but avoid collapsing hole, sticking to improve drilling hole rate and reduce the construction cost due to taking strata as baffle to drill into coal seam.

2 HYDRAULIC FLUSHING TECHNOLOGY AND ITS BASIC PROCESS

2.1 *Action principle of hydraulic flushing*

Hydraulic flushing is a process that high pressure jet break up coal, release large gas and change the state of stress. The primal damage of coal is that high pressure jet which contain high energy break up coal body, formed holes with smaller diameter, then enlarge holes by breaking coal around broken holes under the effect of coal gas pressure gradient and reflection on jet residual energy.

Several holes with larger diameter were rushed out in outburst dangerous coal seam, released a large number of gas and a certain number of coal and formed a certain pressure relief, gas drainage area in coal body during punching process, prevention of outburst usually have taken in the area. Due to water damp fully coal body which decrease brittleness of coal, increase plasticity, reduce stress concentration within coal body, play its comprehensive outburst prevention role.

2.2 *Hydraulic flushing system*

The system consists of punching nozzle, blow-out preventers, drilling rigs, gas-liquid-solid separator,

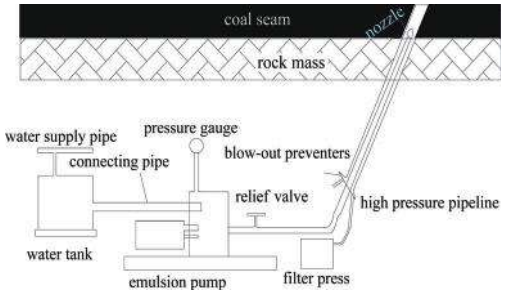

Figure 1. System diagram of hydraulic flushing.

emulsion pump and high-pressure piping. nozzle possess capacity of the secondary crushing, not break coal in the front, but nozzle tail jet is used to remove the pushing coal, control the blocking phenomenon which caused by transient collapsing of coal; the maximum output power, flow and tank capacity of emulsion pump are respectively 31.5 MPa, 200 ml, 1000 L; high-pressure duct with diameter of 31.5 mm was selected as hp piping, system schematic diagram is drawn as Figure 1.

2.3 *Process description*

Hydraulic flushing technology utilizing high pressure water to form a big hole around drill while arouse coal around dirll relieve fully, the gas permeability increased by a large margin, gas within coal seam greatly released, use cement mortar to hole sealing after punching, junction of coal and rock is the depth of sealing hole, finally connect drilling with drainage pipeline to conduct gas drainage for removing outburst.

2.4 *Punching process*

Exit the drill pipe change drill into a special nozzle while change drill pipe into one with smaller diameter which conducive to the discharge cinder, open emulsion pump and drilling machine at the junction of coal and rock, feed drill pipe into drill hole slowly, retrograding drill pipe while punching when reach the max depth, so circulates until ran out of coal and backwater became clear. Then add drill pipe until all coal section rushed out according to such method.

3 ARRANGEMENT OF PUNCHING AND DRILLING

3.1 *Situation of experimental place*

Experimental working face owns a strike length of 370 meters, tendency long is 110 meters, the average coal seam dip angel is 38°, average gas content is 7.89 m^3/t, absolute outflow of gas is 9.2 m^3/min, average pressure of coal seam is 0.82 Mpa. The mine gas pressure is 1.1 times as much as outburst starting condition in case that take 0.74 Ma as outburst starting condition, it became the most serious gas and coal outburst working face. It has to adopt various kinds of gas-prevention measures due to the constantly dynamic phenomenon when drilling on working face. As a result that it appeared orifice, hole collapse, jamming of a drilling tool when carry out bedding drainage drilling on working face, the drill was able to hit the desired depth, the middle of working face appeared empty face between 40 m and 50 m which caused it is hard to realize removing outburst.

3.2 *Drilling hole design*

The test fix up a drill site every 10 meters from south to north in rock concentrated lane, construct strata penetration drilling successively, each drill site owns 4 drills besides No.1 drill site devise 16 drills, the direction, dip and deflection of each drill drilling towards middle working face within the scope of 40 meters until penetrating coal seam as shown in Figure 2.

4 EFFECT INVESTIGATION ANALYSIS OF HYDRAULIC FLUSHING

4.1 *Effect analysis of coal running out*

Complicated geologic structure tectonism not changed combined form of coal seam, but destroyed coal structure of coal itself, which lead coal seam $二_1$ is mellow and fragile, present in powder form. When the hydraulic punching experiment was carried out, the common number drills is 52, the accumulation coal output is 416t, average coal output of each drill is about 8t, calculate

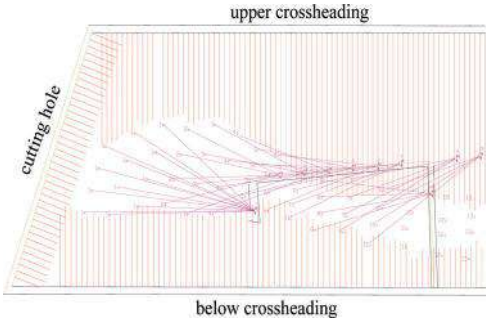

Figure 2. Schematic diagram of strata penetration drilling.

according to discharge of coal, the accumulation punching volume is 301.08 m^3, average punching volume of each drill is about 5.79 m^3, equivalently expand drill with diameter of 75 mm to hole with diameter of 2823 mm, the hole changed stress of coal and release pressure of coal around drill, stress gradient descent, accumulative elastic potential energy released within coal and rock stratum; meanwhile aroused coal seam air permeability increased which make gas within coal discharged and gas expansion accumulatived within coal released (Liu et al. 2005, Jiang & Yu 1996, Liang & Zhang 1997, Xin et al. 2002).

4.2 *Effect analysis of gas reminder quantity and gas pressure*

Determine five covers coal seam original content of gas and proximate analysis (shown in Table 1) before hydraulic flushing, it can be seen from the test results that content of gas is between 5.25 and 7.33 m^3/t, average is 6.29 m^3/t, seen from the data of content of gas by site test that gas occurrence has a tendency to magnify from the shall on to the bottom and travel southward on working face. The coal quality of mine is lean coal, coal seam 二$_1$ belongs to pore development, porosity is between 7.25% and 8.61%, the average is 8.02%, much higher than average porosity of lean coal 4.5%. Namely under the same gas pressure, the bigger coal porosity is, the more free gas amount coal contained (Zhou & Lin 1999), it also explained that low content of gas in coal seam 二$_1$ correspond high gas pressure, so on the basis of preliminary study and combined experiences of other national mining area, used coal seam gas-bearing capacity replaced gas pressure as index for predicting outburst region, set critical value of content of gas as 6 m^3/t through comprehensive analysis. Measured maximum coal seam gas-bearing capacity is 7.33 m^3/t in coal seam 二$_1$ during the test which has beyond critical value for content of gas, this illustrates that eliminating outburst measure is invalid on working face.

Utilizing hydraulic flushing to rush out a certain amount of coal and discharge part of gas which decrease stress of coal around drill, release the stress of coal at different degree that enhanced gas permeability coefficient of gas, increased natural discharge of gas and quantity of drainage, gas emission on working face decreased obviously, it does not appear the phenomenon as jet orifice and sticking after drilling holes along seam on upper and lower roadways of working face, drilling holes along seam can reach desired depth which eliminating empty surface zone with 40–50 m on the middle working face. For verifying effectiveness of this measure, select appropriate location in bottom road, re-determinate of the primary middle blank tape (seen as Table 2). It can be seen from test result that gas pressure of coal seam is less than 0.74 MPa. Coal seam gas-bearing capacity is between 1.88 and 5.93 m^3/t, the average is 3.9 m^3/t, compared with coal seam gas-bearing capacity 6.29 m^3/t without hydraulic flushing, it has decreased by 37.9 percents which below the critical value.

Table 1. Margin settings for A4 size paper and letter size paper.

Sampling location	Buried depth (m)	Mad (%) moisture	Aad (%) ash	Vf (%) volatile	Content of gas of raw coal (m^3/t)	Back calculation of gas pressure (MPa)
Below crossheading cutting hole 5 meters south on working face	360	0.61	11.63	22.19	7.33	1.13

105 working face concentration roadway 2~3, the middle of drill site	5.93	0.21	10.28	17.83	30.174	0.328
50 meters from cutting hole to below crossheading	4.76	0.44	9.97	19.89	30.174	0.328
105 working face, 4~5 concentration roadway, the middle of drill site	1.88	0.22	37.24	15.39	30.174	0.328

Table 3. Summary table of effect assessment of elimination outburst in the working face.

Evaluation method	Evaluation index	Critical value of index	Index range	Effect of removing outburst
Single-phase index	Destruction type	III~V	II~III	Effective
	ΔP	>10	3.5~6.5	
	f	0.5	0.17~0.57	
	Survival gas pressure (MPa)	>0.74	0.27~0.69	
Comprehensive index	D	>0.25	0	Effective
	K	>15	8.54~35.29	
Survival gas content	Survival gas content (m3/t)	>6.0	1.88~5.93	Effective
Gas drainage rate method	Gas drainage rate (%)	>30	31.2	Effective

5 EFFECT EVALUATION OF HYDRAULIC FLUSHING

Using single-phase index method, comprehensive index method, survival gas content method and gas drainage rate method to evaluate effect of removing outburst. Test the effectiveness of removing outburst on working face by hydraulic flushing, the results of assessment is shown in Table 3, it can be seen that after taking measure of hydraulic flushing each index is below critical value, to sum up that hydraulic flushing is effective for removing outburst on working face.

6 CONCLUSIONS

1. It descends the stress gradient of coal around drill by using hydraulic flushing; caused coal gas permeability increased by a large margin while release stress, the gas released and gas pressure gradient fell sharply, not eliminate the stress and gas condition aroused by outburst, and increase outburst resistance restrained by coal body, playing an increasingly important part in comprehensive antioutburst.
2. During investigate of pressure relief effect, the common number drills is 52, the accumulation coal output is 416t, average coal output of each drill is about 8t, calculate according to discharge of coal, the accumulation punching volume is 301.08 m^3, average punching volume of each drill is about 5.79 m^3, eliminate the pressure around drill which make coal seam obtained pressure relief.
3. It can be seen from the contrast before and after the measures that content of gas has decreased from 6.29 m^3/t to 3.9 m^3/t, dropped below gas critical value, eliminate the phenomenon of gas transfinite which explained that hydraulic flushing is effective to eliminate the hazard of outburst on working face. Not only improve the working environment, but also guarantee the safety production on mining faces, the effect of gas control is obvious.

Experimental research on major properties of the sealant to control toxic and harmful gases leakage in coal mine

Ji Li, Fumei Song & Huaiyu Kang
Hebei Province Key Laboratory of Mine Disaster Prevention and Control, North China Institute of Science and Technology, Sanhe, Hebei, China
School of Safety Engineering, North China Institute of Science and Technology, Sanhe, Hebei, China

ABSTRACT: In this paper, exploratory research was done on how polyurethane foam controlled toxic and harmful gases leakage from coalmine. We made 38 groups of experiments by the orthogonal experimental method and single-factor experiment method, which obtained the optimal ingredient ratio. We also prepared polyurethane foam and evaluated its major properties. The results show that sealant can meet the requirements of mechanical properties and high cohesive property under the conditions of coalmines and also has the properties of foaming rapidly, high expansion foaming, dimensional stability, etc. which can be applied well in the prevention and control toxic and harmful gases leakage in coalmine.

1 INTRODUCTION

The working environment of many coalmines is underground, and the conditions are very poor, which have all kinds of toxic and harmful gases and substances, as CO, H_2S, $C0_2$, CH_4, NO_2, SO_2 and coal dust (Shpirt & Goryunova 2009), etc. Some kinds of toxic and harmful gases and substances exist in the coal fissures and pores formed in the production and processing of coal fuels, others exist in the coal seams, roof and floor rock, etc. When the content of these toxic and harmful gases and substances exceeded the critical value, the toxic and harmful gases would be harm to people, and sometimes lead to take place the fire and explosion, which endanger miners' health and safety (Lian 2009).

At present, mining ventilation is the main means to control toxic and harmful gases leakage from coalmines, which discharges the toxic and harmful gases by changing the direction and pressure of the wind, thus the purpose of lowering toxic and harmful gases was achieved (Li & Zhang 2009). Although mining ventilation method has the virtue of controlling toxic and harmful gases exhalation from the mine by wind pressure regulation, it was difficult to meet the requirements of reducing great amount of toxic and harmful gases from the holes with open fractures, cracks, rock wall, mine goaf and the course of blasting for drivage (Li & Shen 2003), etc. In addition, a large number of toxic and harmful gases would be substituted from goaf and hole because of the influence of the ventilation pressure (Xu et al. 2009), even bring out the accidents.

Therefore, in connection with the characteristics of wide areas of toxic and harmful gases leakage, complex rock surface and space condition, and high strength of blasting vibration in coalmines, this paper proposed to use rigid polyurethane foam as sealant and measure the major safety properties of sealant in laboratory. This paper could provide theoretical basis for control toxic and harmful gases leakage in coalmine.

2 THE LABORATORY PREPARATION OF RIGID POLYURETHANE FOAM

2.1 *The composition of experimental materials*

Rigid polyurethane foam is a synthetic material with the characteristics of porosity, low relative density, and high specific tenacity, etc. which is a kind of safety material as sealing material, anchor material in mines, explosion-proof material of fuel tank, filter material (Zhu & Liu 2004), etc.

The polyurethane needs to have some characteristics, as fast frothing, rapid froth coverage, stable froth, high anti-penetrability, antistatic property and low exothermic reaction, etc. for controlling toxic and harmful gases leakage from coalmine. The rigid polyurethane raw material is mainly composed of PAPI (Polyphenylmethane Polyisocyanate), sucrose polyether polyol, foaming agent, catalyst, cross-linking agent, foam stabilizer, frame

retardant (Andrzej et al. 2001, Zhang 2005, Dong et al. 2007), etc.

2.2 *Experimental project*

By orthogonal experiment and single-factor experiment, 38 groups of experimental mix proportion schemes were gotten. According to the proportion schemes, the optimum ratio of experiment was as follows:

PAPI: 50.00% (mass fraction)
Sucrose polyether polyol: 27.82% (mass fraction)
Foaming agent: 7.65% (mass fraction)
Catalyst: 0.49% (mass fraction)
Others: 14.04% (mass fraction)

2.3 *Experimental process*

Mix sucrose polyether polyol, foaming agent, catalyst, cross-linking agent, foam stabilizer, and frame retardant as white material, its appearance was bright yellow viscous liquid.

Mix PAPI and auxiliary material as black material, its appearance was dark brown viscous liquid.

Mix and stir black material and white material rapidly, and then kept them for 40 seconds, the color of reagent began to turn from brown into ivory and began to expand. The foaming time was about 5 minutes (the ambient temperature was: 12.5°C, the humidity was 12.8%).

Measure the foaming volume: it was about 30 times larger than before foaming. The rigid polyurethane shaping material is shown as Figure 1.

Figure 1. Transect of rigid polyurethane foam.

3 THE TEST OF MECHANICAL PROPERTIES OF RIGID POLYURETHANE MATERIAL

The sealant to control toxic and harmful gases leakage needs to have mechanical property of high compressive, tensile and impact force strength, etc. On the one hand, the unconscious damage in the process of operating resulted in large number of toxic and harmful gases leakage, on the other hand, the blasting operations often carried out in coalmines, which can bring out strong vibration force to make a certain pressure on the sealant. If the mechanical strength of rigid polyurethane foam is too low to sustain the pressure, the damage of sealant will lead to great amount of toxic and harmful gases leakage, which can affect the health and safety of workers seriously. Therefore, it is necessary to test the mechanical properties to learn the rigid polyurethane material's compression, tensile and impact force strength, which helps our research on the security during the use of sealant.

3.1 *The test of compressibility*

3.1.1 *Experimental standard and apparatus*

The compressibility test is one of the most important mechanical property indicators of rigid polyurethane foam, which is in according to Test method for compression of rigid cellular plastics (GB 8813-88).

Specimen size: Depth: 50 ± 1 mm; Basal plane: circle, Diameter: 60 mm; Parallelism tolerance of two parallel surface: <1%.

Experimental apparatus: Microcomputer Control Electronic Universal Testing Machine.

Test requirement:

Put each specimen in the center of two flat slabs.

Compress the specimen with 2 mm/min speed rate of the moving slab.

Relative deformation of specimen should reach 10% at most.

3.1.2 *Results*

Specimen description:

Initial specimen: light yellow solid, smooth surface, uniformly distributed pores, not crisp.
Compressed specimen: Surface appeared crimple. The compressed specimen is shown as Figure 2.

When compression began, as the deformation increasing, the initial curve increased significantly, when the relative deformation of specimen reached 10%, the pressure reached the maximum value.

Compression stress when the relative deformation reached 10%.

Figure 2. Compressed specimen.

$$\sigma_{10} = \frac{F_{10}}{S_0} = \frac{2403.8}{2827.44} = 850.2 \text{ kPa} \quad (1)$$

where F_{10} = pressure when to 10% deformation; S_0 = specimen area.

3.2 *The test of tensile strength*

3.2.1 *The test of tensile strength*

The test of tensile strength is according to Test method for tensile properties of rigid cellular plastics (GB 9641-88).

Specimen size: Shape: dumb bell, Total length: 150 ± 0.5 mm, Distance between fixtures: 100 mm, Scale distance (L): 50 ± 0.1 mm, End width: 40 mm, Width of narrow part (l): 25 ± 0.1 mm, Depth (d): 10 ± 0.1 mm.

Experimental apparatus: Microcomputer Control Electronic Universal Testing Machine.

Test requirement:

Clip the specimen to match the specimen axis together with the line of center between upper and lower fixtures.

Use the movable clamp to make the force uniformly distributed on the specimen.

The speed of movable clamp is 5 mm/min.

3.2.2 *Results*

Fracture tensile stress:

$$\sigma_r = \frac{F_r}{d \times l} = \frac{51.5}{10 \times 25} = 206.0 \text{ kPa} \quad (2)$$

where F_r = fracture tensile pressure; d = specimen depth; l = width of narrow part.

Elongation at break:

Put the specimen after break for 3 min, connect the two parts at break, then measure the scale distance.

$$e = \frac{\Delta L}{L} = \frac{0.964}{50} \times 100\% = 1.928\% \quad (3)$$

where ΔL = measurement value minus original value; L = original value.

3.3 *The test of impact strength*

3.3.1 *Experimental standard and apparatus*

Impact strength is an important indicator to measure toughness property of rigid polyurethane material, which is in according to Plastics-Determination of charpy impact strength of rigid materials (GB/T 1043-93).

Specimen size: Length: 120 mm, Width (w): 15 mm, Depth (d): 10 mm, Distance between supporting lines: 70 mm.

Experimental apparatus: XJJ-5 J Type Simple Supported Girder Impact Tester.

Test requirement:

Put the specimen on the plane surface of two supported nipper jaws.

Make the specimen profile near to the blade of supported nipper jaws and the impact line lie in the center of two support pillars.

Choose the pendulum bob with the energy for 1J, then impact the specimen to damage once and read the number of index dial.

3.3.2 *Results*

Impact strength:

$$a = \frac{A}{w \cdot d} = \frac{0.399}{15 \times 10} \times 10^3 = 2.66 \text{ kJ/m}^2 \quad (4)$$

where A = impact energy; w = specimen width; d = specimen depth.

3.4 *The analysis of mechanical properties tests of rigid polyurethane material*

In according to the test of compressive, tensile and impact strength, the relative deformation reached 10%, the compression stress was 850.2 kPa, the tensile strength reached 206.0 kPa and the impact strength reached 2.66 kJ/m^2, as the specimen was collapsing. Thus, the results showed that the sealant could sustain a certain degree of external pressure, tensile and impact force by blasting operations, and meet the mechanical requirements

for the coalmine. Through the visual inspection, we can see that rigid polyurethane foam has a good plasticity, compressed deformation without breaking, regardless of location and constraints, which is a good sealant material to prevent and control toxic and harmful gases leakage in coalmine.

4 THE TEST OF DIMENSION STABILITY

The dimension stability property of rigid polyurethane foam is very important during the process of sealing toxic and harmful gases. In the condition of sealing the gases, if the size of rigid polyurethane foam was volatile, especially contractible trend, it would affect the sealing performance seriously, probably resulting in the toxic and harmful gases leakage again. Therefore, it is very necessary to do the test of dimension stability for rigid polyurethane.

4.1 *Experimental standard and instruments*

The dimension stability test is an indicator of rigid polyurethane foam, which tests according to the test method for Dimensional Stability of Rigid Cellular Plastics (GB 8811–88).

Test method: Keep the specimen for a certain time under the experimental condition, and then measure the change of linear dimension after adjusting the state to standard environment.

Specimen size: Length: 100 mm, Width: 100 mm, Depth: 25 mm.

Experimental apparatus: Temperature Chamber, plastic mould, ruler, vernier caliper, hacksaw, knife.

4.2 *Experimental process*

1. Measure three different locations in each specimen's length (L_1, L_2, L_3), width (W_1, W_2, W_3), and measure the thickness of five different point in each specimen (T_1, T_2, T_3, T_4, T_5). The test location of each specimen is shown as Figure 3.
2. Put the test specimen level on chamber's wire netting, the interval of each at least 25 mm, adjust the temperature to 23~25 °C.
3. After 20 ± 1 hours, remove the specimen from the chamber and place 1 hour.
4. Measure the specimen size after above steps and take a visual inspection.
5. Repeat step (1), (2), (3), (4) for 40 days.

4.3 *Results*

Visual inspection result: Surface condition, shape, and color had no change.

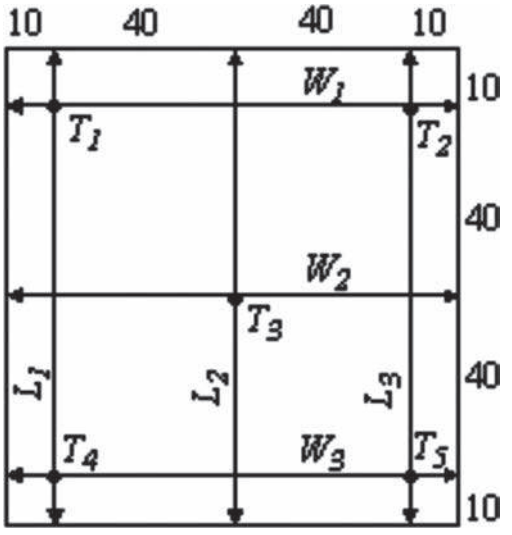

Figure 3. The location of test specimen.

Measure results:

The length, the width and the thickness of specimen had small changes, less than 0.3% for 40 days.

Specimen had a slight inflation trend.

The results show that the rigid polyurethane foam has good dimension stability. Do not worry about the secondary toxic and harmful gases leakage because of the material's good dimension stability.

5 THE TEST OF COHESIVE PROPERTY

As the sealant to control toxic and harmful gases leakage, rigid polyurethane foam should have good gas tightness. If the air tightness was not low enough, it would result in the secondary toxic and harmful gases leakage which would pollute the environment and affect the health and safety of workers seriously. This experiment evaluates the air—sealed of the sealant by measuring the cohesive property between rigid polyurethane foam and coal samples from five different collieries.

5.1 *Experimental test*

Apparatus: Experimental apparatus: Machine for Material Testing (TY8000).

Method:

The test of different kinds of coal samples on identical bonding position: The chosen coal samples come from five high outburst coalmines Pingdingshan Colliery, Zhaogezhuang Colliery,

Tangshan Colliery, Huaibei Luling Colliery, and Xinlong Hongling Colliery. Five coal samples respectively bond with rigid polyurethane foam (the same bonding area), and then measure the maximum compression and shear force of the interface and calculate the bonding strength.

The test of same kind of coal samples on different bonding positions: Select one kind of coal samples with the minimum bonding strength to bond with rigid polyurethane foam on different locations, and then measure the maximum compression and shear force of the interface and calculate the bonding strength.

Specimen size:

Different coal samples test: specimen size: 50 mm × 100 mm × 20 mm, bonding area: 50 mm × 40 mm.

Different locations test: specimen size: 20 mm × 120 mm × 20 mm, bonding length: 10 mm, 20 mm, 30 mm, 40 mm, 50 mm, 60 mm, 70 mm, 80 mm, 90 mm, 100 mm.

5.2 *Results*

Test the bonding level between rigid polyurethane foam and coal samples from five different high outburst collieries. In the case of other environmental conditions are the same, the bonding strength data are shown as Table 1.

The data from Table 1 show that the best bonding level with rigid polyurethane foam is the coal sample from Huaibei Luling Colliery, and the minimum bonding strength is the coal sample from Xinlong Hongling Colliery. The average bonding strength between rigid polyurethane foam and five kinds of coal samples is 427.25 kPa.

Select the coal samples from Xinlong Hongling Colliery to bond with rigid polyurethane foam on different locations (different bonding length, same bonding width as 20 mm), the bonding strength data are shown as Table 2.

The data from Table 2 show that the experimental error is larger on the first location because of the smaller bonding area. The geometric average bonding strength between rigid polyurethane foam and the same coal samples on different boding locations is 387.95 kPa. This data is the average bonding strength between rigid polyurethane foam and high outburst collieries.

The results show that bonding strength is high level between the rigid polyurethane foam and coal samples, which hardly cause the leakage on the bonding location. Therefore, the rigid polyurethane foam has good cohesive property as a sealant to prevent and control toxic and harmful gases leakage in coalmine.

Table 1. Bonding strength test data between rigid polyurethane foam and different coal samples.

Coal samples	Bonding strength (kPa)
Pingdingshan Colliery	421.39
Zhaogezhuang Colliery	415.01
Tangshan Colliery	417.41
Huaibei Luling Colliery	496.33
Xinlong Hongling Colliery	386.15

Table 2. Bonding strength test data between rigid polyurethane foam and same coal samples on different bonding locations.

Bonding locations (mm)	Bonding strength (kPa)
10	594.50
20	419.50
30	401.75
40	389.45
50	398.20

6 CONCLUSIONS

The preparation of rigid polyurethane foam is completed, which can meet the requirements of certain mechanical properties, dilatability, dimension stability and low permeability.

1. The rigid polyurethane foam has some good physical feature, as rapid foaming, high multiple foaming, and well-distributed, compact froth, which can meet the practical requirements of the site.
2. The rigid polyurethane foam can meet the requirement of mechanical properties. As the relative deformation reaches to 10%, its compression strength is about 800.0 kPa, as the specimen was collapsing the tensile strength reached 206.0 kPa and the impact strength reached 2.66 kJ/m^2.
3. The rigid polyurethane foam has good dimensional stability, less than 0.3% of its deformation for 40 days in experimental state.
4. The rigid polyurethane foam has good cohesive property, which the average bonding strength between rigid polyurethane foam and high outburst collieries is 387.95 kPa. Therefore, the rigid polyurethane foam as the sealant can control toxic and harmful gases leakage in coalmine safely and effectively.

ABSTRACT: Field observation has proved that the main methane resources of the 12# mining faces of Nanzhuang Coal Mine came from the upper adjacent coal seams. In order to drain this methane, lots of measurements has been undertaken. However, the drainage efficiency was low and methane emission amount was still large. In this paper, a newly developed borehole arrangement for draining the gas in the fractured zone was described. The core of this arrangement was the cooperation of the high-level and low-level boreholes based on the methane enrichment regularity of the fractured zone. Subsequently, this newly developed arrangement was applied in mining faces of 12# coal seam in Nanzhuang Coal Mine. The field observation demonstrated that this arrangement profoundly enhanced both the drainage efficiency and safety mining. More importantly, with utilizing the drained methane, Nanzhuang Coal Mine obtained substantial economic benefits and did paramount work for the greenhouse gas control.

1 INTRODUCTION

Coal Seam Methane (CSM) or coalbed methane (CBM) is the naturally occurring gas in coal seams, which is normally considered as the cause of coal mine disasters like coal and gas outburst and methane explosion (Wang and Xue, 2008). But recently, the nature of CSM as the clean and efficient energy has been progressively understood (Chen et al., 2012). Besides, as a greenhouse gas, CSM has over 20 times the greenhouse effect and 7 times more harming of the Ozone Layer compared to carbon dioxide (Chen et al., 2012).

CSM drainage and utilization have been conducted all over the world, especially in China. China has abundant CSM resource, which is estimated at 36.8×10^{12} m^3 within the depth of 2000 m (Cheng et al., 2011, Wang et al., 2012a). In order to improve the safety and efficiency in mining and protect the environment, most coal mines in China drained the CSM (Li et al., 2007, Liu et al., 2009a, Liu et al., 2009b, Liu et al., 2010, Lu et al., 2009, Lv et al., 2012, Sang et al., 2010, Wang et al., 2012a, Wang et al., 2008, Zhou, 2012, Zhou et al., 2012), and the early pioneers were the coal mines in Yangquan Mining Area.

Yangquan Mining Area has multiple coal seams and abundant CSM, but the methane was difficult to drain. Therefore, methane emission in coal mines in Yangquan Mining Area was comparatively high. Statistical analysis of methane sources in pairs of coal mines showed that the adjacent coal seams were the main sources of methane emission of mining faces, and whether this part of methane could be appropriately controlled would significantly impact the safety mining. Taken mined faces of 12# coal seam in Nanzhuang Coal Mine for example (Wang et al., 2012b), many years' field observations have demonstrated that the main methane sources of mining faces of 12# coal seam were the working coal seam, overlaying adjacent coal seams and lower adjacent coal seams, while the methane quantity emitting from the overlaying adjacent seams, which was the focus of drainage, accounted for more than 85% methane emission of mining faces of 12# coal seam. For the purpose of draining this part of methane, a single sort of boreholes were arranged in tail roadway terminating at 9# coal seam. However, the drainage efficiency was not very high and methane emission from the fractured zone was still high. In order to reverse this trend, measures like increasing air volume and limiting the mining speed had been carried out. In such a case, however, not only the production efficiency was reduced, did the drainage efficiency be little enhanced. Thus, new technologies for controlling

the gas emitting from overlaying adjacent seams of 12# coal seam must be developed.

In this paper, a new borehole arrangement to drain the gas in mining induced fractured zone was depicted. The essence of this arrangement regime was the cooperation of the high-level boreholes and the low-level ones in terms of the evaluation on the methane enrichment regularity of the fractured zone which is divided into two regions by the thick and stiff Medium Sandstone. Subsequently, this newly developed borehole setting was applied in mining faces of 12# coal seam in Nanzhuang Coal Mine. This borehole arrangement significantly enhanced the drainage efficiency and safety mining of the applying faces. More importantly, with utilizing the drained methane, Nanzhuang Coal Mine obtained substantial economic benefits and did paramount work for the greenhouse gas control.

2 DESCRIPTION OF THE COAL GEOLOGY CONDITION OF NANZHUANG COAL MINE

Nanzhuang Coal Mine is located in southern Yangquan City, Shanxi Province, China, which is 12.59 km^2 in terms of mine area and 200 t/y of approved production capacity. The coal-bearing strata are Shanxi Formation (Lower Permian) and Taiyuan Formation (Upper Carboniferous), and the minable coal seams are 3#, 6#, 12# and 15# coal seams, among which the 3# and 6# coal seams has been mined. The stratigraphic column of Nanzhuang Coal Mine (partial) is shown in Table 1.

Table 1. Stratigraphic column (partial).

Lithology	Thickness (m)
8# Coal Seam	0.31
Medium Sandstone	15.93
9# Coal Seam	0.28
Mudstone	6.71
Medium Sandstone	13.38
10# Coal Seam	0.18
Mudstone	2.86
K_4 Limestone	1.69
11# Coal Seam	0.36
Fine Sandstone	3.80
Sandy Mudstone	3.00
Mudstone	3.00
12# Coal Seam	1.22
Mudstone	1.98
Fine Sandstone	3.33
Mudstone	1.98
K_3 Limestone	3.06
13# Coal Seam	0.31
Sandy Mudstone	3.8
Fine Sandstone	11.37
Sandy Mudstone	6.26
K_2 Limestone	5.3
14# Coal Seam	0.53
Fine Sandstone	5.38
Sandy Mudstone	8.3
15# Coal Seam	5.86

The coal seam addressed in this paper is 12# coal seam, which is 1.22 m high in average and inclines about 6°. Mining faces of 12# coal seam, of which the designed length and mining height were respective 180 m and 1.5 m, applied the complex mechanical strike retreating coal mining technology. The ventilation system of these faces were consisted of three roadways, namely a rail roadway as the return airway, a haulage roadway as the intake airway and a tail roadway as the special gas drainage gateway.

3 PRACTICE OF THE NEW FRACTURED ZONE GAS DRAINAGE TECHNOLOGY IN NANZHUANG COAL MINE

3.1 *Deficiencies of the previous fractured zone drainage setting*

Before 2009, while mining 12# coal seam, the boreholes were drilled in the special gas drainage tunnel of the mining faces to the 9# coal seam, which is in the upper fractured zone and about 35 m upper to 12# coal seam. However, this borehole arrangement could not fully mitigate the methane emission from the upper fractured zone. Taking NO. 4604 mining face as example, with mining proceeding, the methane emission increased from 10 m^3/min to 70 m^3/min while the drained volume was only 36 m^3/min, and the average methane concentrations in mining face, return airway, upper corner, and tail roadway were 0.7%, 1.0%, 1.0%, and 3.0%, respectively, which were apparently beyond the permitted methane concentrations of coal mines in China (Cheng et al., 2011). Due to these high concentrations, which were readily cause methane explosion, Nanzhuang Coal Mine took measures such as enhancing the ventilation volume from 1240 m^3/min to the permitted maximum 1650 m^3/min, reducing the mining speed, and so on. Subsequently, however, the situation was of little improvement.

From field observations, it was found that the methane concentration of the mining face increased substantially after the overlaying strata cracking which could be monitored by the overburden stress

variation. We analyzed that two causes resulted in this phenomenon. One is the closely upper methane occurring zone consisted of 11#, 10# coal seams and the K_4 Lime stone. After mining of the 12# coal seam, this region cracked rapidly and thus the methane spontaneously desorbed and migrated to the mining faces subject to the impact of the negative pressure of ventilation. The other is the inefficiency of the drainage setting. Due to the thick Medium Sandstone and Mudstone under 9# coal seam, the negative pressure of the drainage boreholes terminated in 9# coal seam could hardly affect the region around 10#, 11# coal seams and thus the methane in this area.

3.2 *Development of the new drainage arrangements*

In terms of the interpretations above, we modified the previous drainage setting and proposed a new drainage arrangement, as depicted in Fig. 1.

With the field observations and numerical simulations (Wang et al., 2012b), we concluded that the fractured zone of 12# mining seam was partitioned into two regions by the thick and stiff Medium Sandstone under 9# coal seam, where the upper one consisting of 8# and 9# coal seams was called the high gas enrichment zone and the lower one consisting of 10#, 11# coal seams and K_4 Limestone was called the low gas enrichment zone, as depicted in Fig.1 (a). The influence of gas in the low enrichment zone on the mining face was almost instantaneous after the overlaying seams cracked, while the impact of the gas in high enrichment zone was hysteretic. Based on these understandings, we determined to arrange different sorts of boreholes to drain the gases in these two zones, respectively. As is illustrated in Fig. 1, the high-level boreholes in the tail roadway were maintained, while new low-level boreholes were drilled in the return airway to extract the gas around 10# and 11# coal seams. Besides, in order to properly utilize the negative pressure induced by ventilation, the orientation of low-level boreholes was toward the wind.

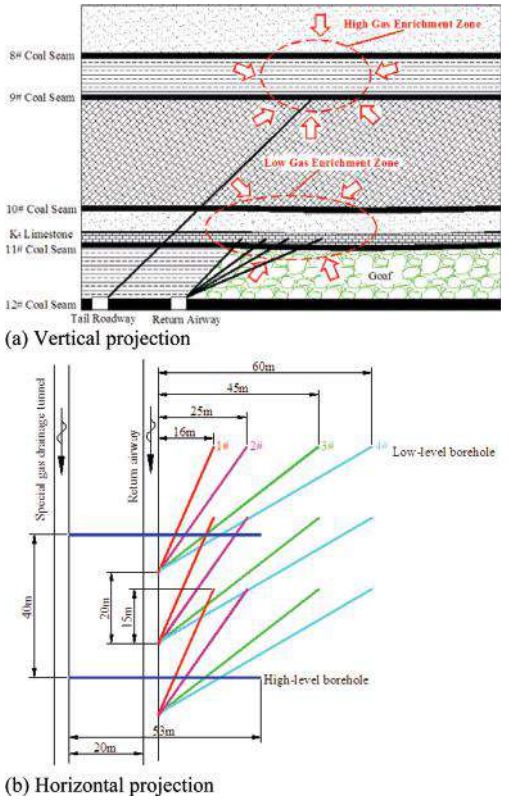

Figure 1. Arrangement of the new drainage boreholes.

3.3 *Application results*

The newly developed borehole arrangement was firstly applied in the NO. 4611 working face, and the paramount implication was the improvement for the safety mining. With this arrangement, the methane concentrations in mining face, return airway, upper corner, and tail roadway decreased to 0.5%, 0.5%, 0.7%, and 1.8%, respectively, which were lower than the permitted concentration of coal mines in China and far lower than the explosion concentration. Besides, through applying this drainage scheme, the drained volume increased to more than 80 m^3/min which accounted for more than 85% of the total methane emission volume.

Another improvement was the increase in coal production. After applying the new cooperative borehole setting, the mining speed increased from 2–2.5 m/d to 4–5 m/d, and the coal production per month enhanced from 20 thousand tons to more than 4o thousand tons.

Besides, Nanzhuang Coal Mine stored the drained methane and then utilized these gases for economic and environmental concerns, and these will be presented in the next section.

4 UTILIZATION OF THE DRAINED METHANE IN NANZHUANG COAL MINE

Due to the multiple overlaying coal seams and their high methane content, the concentration of the drained methane of the 12# coal seam was generally greater than 40% and could be directly applied for power generating. Therefore, Nanzhuang Coal Mine built a set of power generators with capacity

of 10 × 500 kW. From 2009, Nanzhuang Coal Mine has generated electricity about 47 million kW•h, all of which was utilized for self-consumption and nearly 30 million RMB was saved.

Additionally, Nanzhuang Coal Mine utilized these gases for commercial concern, such as selling to the fuel enterprises, and more than 30 million RMB was earned. Besides, China government subsidized the enterprises who utilized coal mine methane or coalbed methane, and with this subsidy, Nanzhuang Mine received 20 million RMB.

Furthermore, the negative impact of methane on environment has attracted more and more attention all over the world recently. It has demonstrated that methane has over 20 times the greenhouse effect and 7 times more harming of the Ozone Layer compared to carbon dioxide (Wang et al., 2012a). Nanzhuang Coal Mine annually utilized about 30 million normal cubic meters methane which were mainly converted to the significantly lower-effective greenhouse gas carbon dioxide and water.

5 CONCLUSIONS

With the field observations and simulation results, it was found that the fractured zone of 12# mining seam was divided into two regions by the thick and stiff Medium Sandstone under 9# coal seam, where the upper one consisting of 8# and 9# coal seams was called the high gas enrichment zone and the lower one consisting of 10#, 11# coal seams and K4 Limestone was called the low gas enrichment zone. The influences of gas these two regions on the mining faces of 12# coal seam are totally different, where the lower one was almost instantaneous after the overlaying seams fell, while the upper one was hysteretic. Based on these understandings, a new borehole arrangement for draining the gas in mining induced fractured zone was developed. The high-level boreholes in the tail roadway were maintained, while new low-level boreholes were drilled in the return airway for extracting the gas around 10# and 11# coal seams. Besides, in order to properly utilize the negative pressure induced by ventilation, the orientation of low-level boreholes was toward the wind.

Through applying the newly developed drainage scheme, two direct positive benefits were obtained, one was the decrease of the methane concentration in mining faces and the related airways, the other was the increase in mining efficiency raising from 2–2.5 m/d to 4–5 m/d. Besides, Nanzhuang Coal Mine developed a series of utilization schemes such power generation, selling as fuel gas, self-consumption as fuel gas and so on. From 2009, Nanzhuang Coal Mine has generated electricity about 47 million kW•h, all of which was utilized for self-consumption and nearly 30 million RMB was saved. By selling outside, more than 30 million RMB was earned. In addition, China government subsidized the enterprises who utilized CSM, and with this subsidy, Nanzhuang Mine received 20 million RMB. Furthermore, utilization of CSM of Nanzhuang Coal Mine implied a profound significance in greenhouse gas control in that methane has over 20 times the greenhouse effect and 7 times more harming of the Ozone Layer compared to carbon dioxide.

ABSTRACT: This paper is to research an application of the multiplicative seasonal model to forecast the total number of China's coal mine accidents. By the empirical analysis on the data of coal mine accidents from January 2006 to December 2010, an accepted multiplicative seasonal forecasting model ARIMA(4, 1, 1)(1, 1, 1)^{12} is built up after differing the series to be stationary and estimating the order and parameters of the model. Furthermore, the test of this multiplicative seasonal model shows that it has a desirable fitting effect on the data of coal mine accidents. At last, this model is applied to forecast the number of national coal mine accidents from January 2010 to December 2010, and the forecasted values have a high accuracy when compared to the actual data.

1 INTRODUCTION

With a high attention from China's government on the safety production of coal mine, the situation of it turned better gradually. Besides, China has enacted a series of law, rules and technical regulations to promote the development of the safety production of coal mine, which later plays a crucial rule to reduce the number of coal mine accidents. For example, an emergency notice was issued in August 2005 to strictly close down some illegal coal mines which don't meet the requirement of producing safely. And then a series of law was also enacted to strengthen the fundamental safety management of small coal mines and national key coal mines, to strengthen the action of monitoring the status of gas, and to clear the usage of the safety fees which includes a measure that the upper limit of the original standard is changed to be the lower limit of the new standard. The law also allows companies to raise the level of the extraction standard, to strengthen the management of rating agencies and the training of safety production. These measures made the number of coal mine accidents decrease even if the volume of the production of coal has constantly increased since 2006. To research the regulations of the accidents, the paper takes the Seasonal ARIMA model to forecast, and the result shows that the forecasted values are in a high accuracy and this model will guide the future work.

2 THE MULTIPLICATIVE SEASONAL MODEL

2.1 *The introduction of the multiplicative seasonal ARIMA model*

The time series analysis is a statistical method to reveal the dynamic law of a system through dynamic data (Box 2005). Its core idea is that, with the finite number of data in the series, a model could be created to precisely reflect the dynamic relationship hided in the time series, and then to forecast the future.

The model of ARIMA is one of the stochastic time series analysis methods (Xue 2011, Zhang 2005). Stochastic time series includes the stationary time series (its statistical feature does not depend on time) and the nonstationary time series. To the stationary time series, we could analyze it by Autoregressive Processes (AR(p)), Moving Average Processes (MA(q)) and Mixed Autoregressive Moving Average Processes (ARMA(p, q)). Similarly to analyze the nonstationary time series, this series is initially to be computed by the d-th order difference, and then erect the ARMA model, namely the ARIMA(p, d, q) model. Accordingly,

the Multiplicative Seasonal Model is a combination of the stochastic seasonal model and the ARIMA model.

Also, a time series changing seasonally couldn't be modeled by ARMA immediately. Firstly, it should be differed to remove the seasonality of the series, and the length of one difference step is one seasonal cycle. Generally, if the series is processed by a D-th order difference the cycle length of which is s, the seasonality will almost be removed. Furthermore, if the series needs to be turned stationary by a d-th order difference before it's impacted by the seasonal difference, a model called the Multiplicative Seasonal Mod-el ARIMA(p, d, q) $(P, D, Q)^s$ could analyze the original series, and the model is described as below:

$$\phi_p(B)\Phi_P(B^s)\nabla_s^D y_t = \theta_q(B)\Theta_Q(B^s)u_t$$

In the equation, p represents the order of Seasonal Autoregressive Processes, and q represents the order of Seasonal Moving Average Processes. Moreover, $\Phi p(B^s)$ and $\Theta p(B^s)$ respectively represent the operators of the Seasonal AR(p) and MA(q) models.

2.2 *The process to build the multiplicative seasonal model*

The modeling process can be divided into three concrete steps: smoothing the data; identifying a process and estimating the order and parameters; testing the model.

1 Smoothing
This step can be completed by differing or taking the data's logarithm.

2 Identifying and estimating
In the step of identifying, we generally determine the order and estimate the parameters by the Box-Jenkins method. That is to say, we could obtain the results through the analysis of the autocorrelogram and partial-autocor-relogram. And the length of season could also be learned from the background of practical applications.

3 Testing
The methods to judge whether the model is suitable are the goodness of fitting tests, one classical method of which is to make an analysis of the residual series. If the residual series is not the white noise series, it bespeaks that the amount of effective information is still left in the residual series. As a result, the model needs to be improved until the residual series is squeezed to be the white noise series.

3 EMPIRICAL ANALYSIS

3.1 *The sample selected*

The data in this paper show the total number of coal mine accidents happening in China from January 2006 to December 2010. (The data are from "The report of national coal mine accidents analysis in 2010" published by the Department of Accident Investigation at State Administration of Coal Mine Safety). The data processed to model are from January 2006 to December 2009, and the data of 2010 aim to be compared with the forecasted data, see table 1.

As shown in Fig. 1, the original data are drawn as a line graph. The series is non-stationary and has an obvious descending trend, including a seasonal fluctuation the cycle of which has 12 months.

We easy know the original data are drawn as a line graph. The series is non-stationary and has an obvious descending trend, including a seasonal fluctuation the cycle of which has 12 months.

Dec	192	165	61	113	42

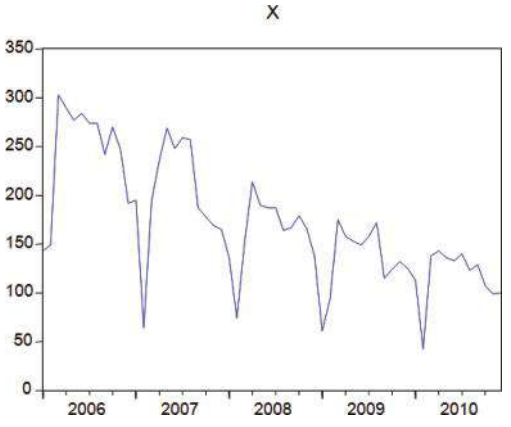

Figure 1. The original series.

3.2 *Processing data*

To remove the trend and alleviate the fluctuation of the original series, the series should be taken by natural logarithm (log(x)) and then differed between the adjacent points (log(x) and log(x(-1))). After calculation, a new series is created, which is noted as ilx, namely ilx = log(x)-log(x(-1)). From the autocorrelogram and partial autocorrelogram of series ilx, the trend in series ilx is almost removed. However, when k is equal to 12, the coefficients of autocorrelation and partial autocorrelation are significantly not equal to 0, which indicates that the seasonality exists in series ilx. So, a seasonal difference should be exerted on the series ilx, which leads to a new series called silx (silx = ilx-ilx(-12)). The result from the autocorrelogram and partial autocorrelogram of series silx shows that the seasonality in series ilx doesn't exist in series silx.

Now the next step is to test whether the hypothesis is accepted that the mean value of the series is equal to 0.

To further test whether the series is stationary, a formal method called unit roots test is provided. The results of unit roots test can be seen in table 2.

3.3 *Identifying a model*

As the trend in the original series log(x) is removed by a first-order difference, the value of d should be equal to 1; And similarly, the seasonality in the series ilx disappears after it's processed by a seasonal difference, so D is also equal to 1 and the ARMIA(p, d, q) $(P, D, Q)^s$ is thereby selected. After observing the autocorrelogram and partial-autocorrelogram of series silx, we prefer to pick q = 1, p = 2 or p = 3. Compared to the non-linear estimation possessed by MA(q) and ARMA(p, q) processes, the AR(p) model as a linear equation is easier to estimate, explain and forecast. Consequently, in the practical process of modeling, we prefer the high order AR(p) processes to the MA(q) and ARMA(p, q) processes. According to the analysis above, the candidate combinations of (p, q) include: (3, 1), (4, 0), (4, 1). When k is 12, the sample's coefficients of autocorrelation and partial-autocorrelation are significantly not equal to 0, so P = Q = 1.

		t-Statistic	Prob.*
Augmented dickey-fuller test statistic		–2.582438	0.0113
Test critical values:	1% level	–2.630762	
	5% level	–1.950394	
	10% level	–1.611202	

3.4 *Modeling and testing*

By the econometric software Eviews 6.0 (Yi 2011), it can build models immediately and figure out the parameters and coefficients conveniently. For example, in the modeling of ARIMA(4, 1, 1)$(1, 1, 1)^{12,}$ we choose the option of Quick/Estimate Equation in main menu, and open equation definition dialog and enter silx ar(1) ar(2) ar(3) ar(4) ma(1) sar(12) sma(12)

Among the variables above, sar(s) and sma(s) are respectively the variables in the seasonal Autoregressive part and the seasonal Moving Average part.

After calculation, each model meets the conditions of stationary and invertible in the ARMA modeling process. At the same time, the models are reasonably defined and desirably fitting the data. Among these models, the AIC value of the 3rd model is the smallest. Therefore, it is appropriate to choose the 3rd model ARIMA(4, 1, 1)$(1, 1, 1)^{12}$ as the final model to forecast.

The diagnosis of one model is accomplished by the check for of residuals. If the residuals is the white noise series, this model satisfies the requirement that nearly all the effective information in this series has been extracted out. Otherwise, it

needs to be furthermore improved. After the residual analysis on the Multiplicative Seasonal model above, which includes the unit root test taken to the residuals and the analysis of the autocorrelogram and partial-autocorrelogram of the residues, we conclude that the residues is both stationary and totally stochastic, and the model built up well fits the trend of the data in the series.

3.5 *Forecasting*

We apply the ARIMA(4, 1, 1)(1, 1, 1)^{12} model to forecast the number of national coal mine accidents from January 2010 to December 2010. The forecasted value is shown in table 4.

The mean absolute percent error MAPE, which is 9.99 less than 10, indicates that the forecasted values are in a high accuracy. Besides, Thell Inequality Coefficient TIC is 0.057, and Bias Proportion BP 0.059 and Variance Proportion VP 0.005 are relatively small while Covariance Proportion CP 0.935 is relatively large. All these parameters suggest that the result of forecasting is desirable. See the Figure 2.

4 CONCLUSION

Compared to ordinary time series models, the Multiplicative Seasonal Model needs more historical data, and the Multiplicative Seasonal Model can be applied to a wider field because data in daily life always have an obvious trend and seasonal features. Therefore, the Multiplicative Seasonal Model can well solve such problems that involve some issues about forecasting, and as well as reach a high precision. The model in this paper, ARIMA (4, 1, 1)(1, 1, 1)^{12,} well matches the monthly changing number of national coal mine accidents. Moreover, the more historical data, the more accurate the forecasted result is. All above, the Multiplicative Seasonal Model is a practical tool for us to forecast or to apply in many other fields.

Monitor and control node in coal production safety based on LonWorks Fieldbus

Tao Zhang
North China Institute of Science and Technology, Yanjiao, Sanhe, Hebei, China

ABSTRACT: The paper introduces the monitor and control system in coal production safety which basing on LonWorks Field Bus firstly. On the base of the importance of the measure and control node which basing on LonWorks, the paper discusses the design process of the measure and control node which basing on LonWorks technology. The paper proposes the hardware and software block diagram of the measure and control node which basing on LonWorks technology. The designed node has application value on the monitor and control system in coal production safety.

1 INTRODUCTION

Since 2000, in need to continuously improve the national coal mine safety production requirements and the enterprise own development, China's high gas coal mine has equipped with a monitoring system of coal mine safety production.

The monitoring system of coal mine safety production is one of the important guarantees to improve the mine safety production level and production safety management efficiency, is an important way to improve China's coal mine safety, efficient, orderly production, and is the route one must take our coal mine enterprises to modern management.

With the rapid development of electronic technology, computer software and hardware technology, automation technology, and the need of enterprise development, the main domestic research institutes and manufacturers have launched a series of coal mine production safety monitoring system. The coal mine safety production monitoring system including monitoring and control system of coal mine safety production is dominated by a single microcomputer, including the Distributed Control System (DCS) based on the monitoring system of coal mine safety production, and other types of coal mine safety integrated and digital network monitoring and management system.

But DCS system has its inherent shortcomings, mainly DCS systems of different manufacturers with different communication modes, resulting in between DCS and DCS, DCS from different manufacturers and the Intranet/Internet network are difficult to realize network interconnection and information sharing, therefore, from this perspective, DCS system is not open (Li Z.J. 2006).

2 MONITORING AND CONTROL SYSTEM BASED ON FIELDBUS

Fieldbus Control System (FCS) is the intelligent field instrument developed. It was designed by digital communication instead of 4–20 mA analogue transmission technology, but with the integration of fieldbus and intelligent instrument control (instrument calibration, configuration control, diagnosis, alarm, record) development, resulting in a hitherto unknown revolution in control field.

Distributed Control System (DCS) of communication to achieve a closed system with a private network, and the Field bus Control System model (FCS) breaks through the defects caused by DCS, the closed, proprietary solutions become based on open, standardized solution.

FCS can take from different manufacturers and abide by the automation equipment with the same protocol specification, through the field bus network connected into a system, to achieve various functions integrated automation; at the same time, the distributed system structure of traditional DCS combination of concentrated and dispersed, into a new field bus based on distributed structure, in the traditional DCS network under a and then introduce a fieldbus network layer, electronic equipment, a variety of intelligent I/O module underlying intelligence and various kinds of intelligent instruments through the field bus control network layer (Wang C.L. 1999).

In the field bus control system, sensor measurement, compensation calculation, engineering quantity processing and control functions in the field of equipment complete, relying on the field devices to complete the basic functions of automatic control, operation state and can at any time

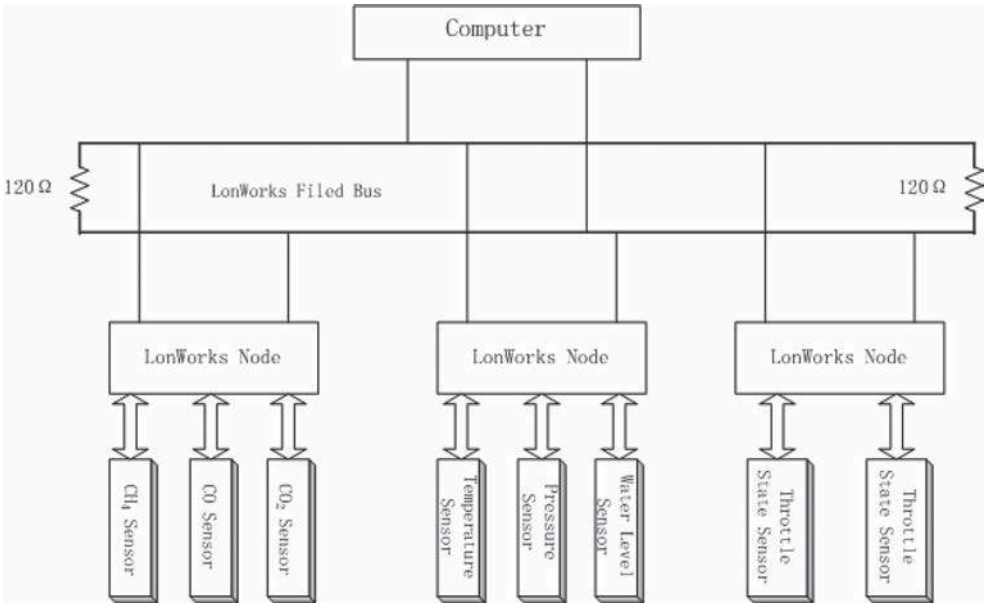

Figure 1. The monitoring and control system of coal mine safety production based on LonWorks filed bus.

diagnostic equipment, complete the implementation of decentralized control.

LonWorks is a local operation network the United States of America Echelon company launched in 1992, all the seven layer model of the communication protocol using LonTalk to support OSI/RM, LonTalk protocol for the management of LON network by hardware and firmware neuron chip.

The application of LonWorks technology using object-oriented design method, through the network variables to simplify the design of network communication for parameter settings, greatly shorten the product development cycle. At present, the LonWorks bus has high reliability, safety, easy to realize and interoperability advantages, make LonWorks products in a very wide range of applications, LonWorks bus has become a field of mature bus.

In this paper, Figure1 shows the monitoring system of coal mine safety production of LonWorks bus (Wang R.L. & Lei B. 2004).

3 INTELLIGENT CONTROL NODE BASED ON LONWORKS FIELD BUS

3.1 *Summary*

LonWorks measurement and control node has two basic functions: one is connected with various sensors in the industrial field, control the working status of a sensor, or read the industrial field measurement data; the two is connected with the upper PC, accept all kinds of the PC's control command, or to the upper PC transfer various industry scene measurement data.

The principle and the working process of LonWorks measurement and control nodes connected to the various sensor is basically the same, according to the LonWorks measurement and control nodes connected with a temperature sensor as an example, the LonWorks control node of temperature measurement (Zhang T. & Jiang J.P. 1999).

3.2 *Hardware design*

Figure 2 shows the hardware structure of LonWorks temperature measurement node (Liu J.H. 1999).

Micro controller selects the neuron chip as the core components of the LQICLON control unit, with 24 bit analog to digital converter ADS1216, uses AD590 as temperature sensor, and comprises an optoelectronic isolator PS2501 unit.

Data acquisition and control module LQICLON to realize the LonWorks technology, it can complete the acquisition and equipment control switch of various industrial standard digital signal, it has 12 digital inputs, 12 digital output, and a light emitting diode display input/output state, has the high reliability, the hardware connection is simple, the software is easy to the advantages of programming.

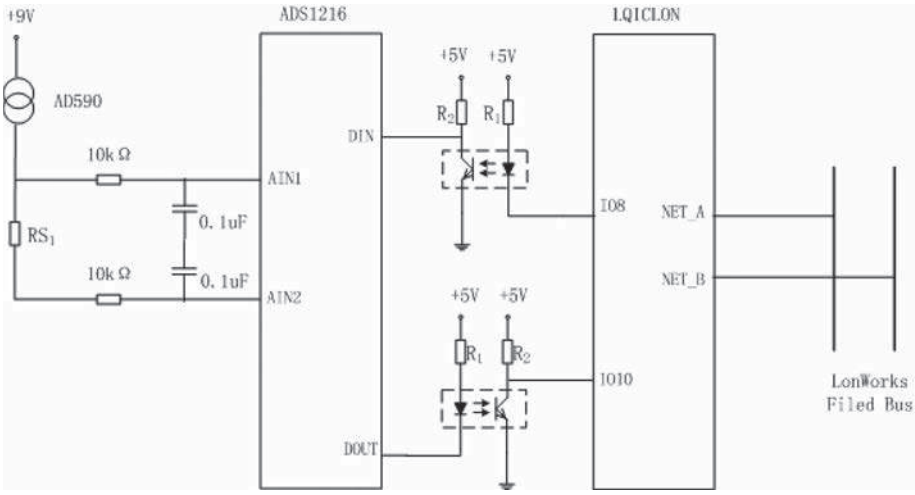

Figure 2. Hardware structure chart of LonWorks temperature measurement node.

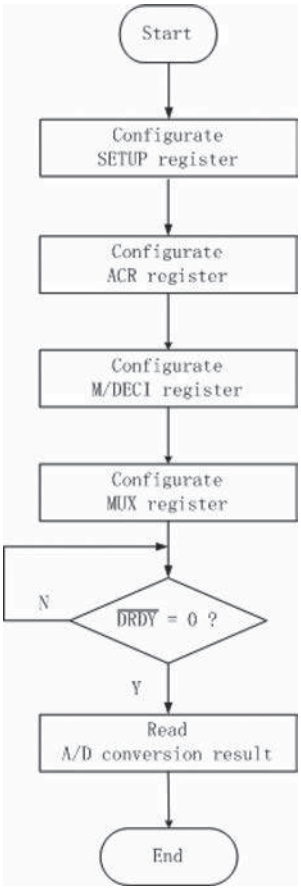

Figure 3. Subroutine structure chart of LonWorks temperature measurement node.

Thermocouple AD590 as the temperature sensor, the need for the cold end temperature compensation.

The connection between AD590 and ADS1216 thermocouple analog-to-digital converter by RC low-pass filter, in order to reduce the impact of temperature simulation of harmonic signal.

24 bit resolution ADC ADS1216 with high conversion accuracy, it has 8 single-ended input channels or 4 channels of differential input channels. This design uses ADS1216 AIN1 and AIN2 to form a differential input channels, to receive the temperature simulation measurement signal (Yang X.H. 1999).

3.3 *Software design*

LonWorks temperature measurement node function is equivalent to the coal mine safety monitoring and control system of underground substation, so the corresponding function it should also have the coal mine substation, and the characteristics of LON fieldbus.

LonWorks temperature measurement node program mainly includes the main program, temperature measurement program, communication program (Yang Y.H. 1999).

In the design of these programs, most of the procedures described in the literatures are, here no longer say. This paper only gives the temperature measurement subroutine, as shown in Figure 3.

4 CONCLUSION

The paper first gives the framework of monitoring system in coal mine safety production using LON

bus, for the temperature control of LonWorks node system is discussed and designed in detail, the design block diagram of hardware circuit and software design of LonWorks temperature measurement and control nodes are given.

The advanced LON bus technology is applied in the intelligent measurement and control system, greatly improve the reliability of the system; the independent development of international standard based on intelligent node MCU, not only saved a lot of money, but also the purchase of similar equipment in general, can save a lot of R & D costs, for coal mine safety production monitoring system based on LON bus based on the practical application value.

ABSTRACT: The study was conducted based on stope overburden bed-separation grouting along the dip. Adopted two methods, theoretical analysis and indoor analogical simulative experimentation, proposed subsidence reducing technique by continuously filling grouts into stope overburden bed-separation along the dip. Its core was to completely cancel pillar between faces, to realize overburden's sufficient mining before grouting, to maintain continuity of bed separation zone. On the premise of reducing quantity of grouting and drilling works, achieved relatively ideal subsidence reducing effect. In the end, this technology was verified based on practical background, considered that within the application, the technology had a feature that the mining degree was higher, grouting effect was more evident, working section recovery was increased and drilling quantity was reduced. Therefore, considered that this technology had a certain application value.

1 INTRODUCTION

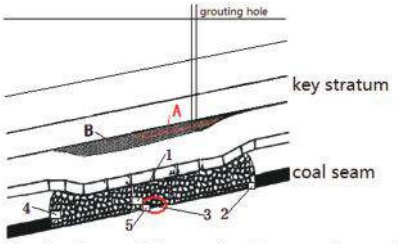
In 1980s, industrial test of overburden bed separation filling technology was first conducted in Lao Hu-tai coal mine, Fushun Mining Bureau and succeeded (Xueli Fan 1998). Then industrial tests of bed separation filling technology were successively conducted in dozens of coal mines such as Datun Xuzhuang, Kailuan Tangshan, Xinwen Huafeng, Yanzhou Dongtan coal mine, etc. And some achievements were made (Yimeng Meng & Zhenxian Lv 1993, Yaping Zhong & Yanfa Gao 2001, Weijia Guo & Guanghan Shen 1995, Dongjian Zhang & Hengqing Guo 1999, Huaxing Zhang, Zunyi Wei 2000).

The fundamentals of reducing surface subsidence by grouting is to make use of space of bed separation in overburden generated during strata movement, inject materials through borehole into space of bed separation to support overburden, thus to slow down spread of strata movement towards surface. The premise of application of the technology was that a relatively large space of bed separation could form in overburden after mining, the rational arrangement of grouting holes was the key of the technology, but dynamic distribution rules of bed separation were not studied thoroughly. Therefore, conditions for generation of bed separation were discussed by many domestic scholars (Yuzhuo Zhang & Liliang Chen 1996, Weijia Guo et al. 1995, Minggao Qian et al. 1996).

In reference 10, based on key stratum theory, bed separation was proved to occur mainly below the key strata by experimental and theoretical researches, and dynamic rules of bed separation were revealed.

In references 11 and 12, an in-depth study was conducted of separation's position and volume, dynamic developmental characteristics as well as affecting factors during strata movement. It turned out that overburden bed separation mainly occurred below the key strata, and the highest bed separation space stopped right below the primary key stratum. The length and the largest volume of separation zone after initial rupture of the key stratum were only 25%–33% of that before initial rupture of the key stratum. Therefore, bed separation filling technique should be applied before initial rupture of the key stratum, and kept the primary key stratum from breaking.

References 16 discussed issues about the space-time laws of the bed separation's development, the method of evaluation of subsidence reducing effect and application of bed separation grouting to reduce subsidence in coal mining under buildings. Considered that under the same conditions, the height of bed separation changed with the size of gob. When the gob size reached sufficient mining, the height of bed separation reached its maximum; Accurate evaluation of grouting effect should base on a comparison between measured volume of subsidence basin after grouting and that didn't



grout in the same mining district. Most lengths of working faces along the dip were between 100 m and 200 m, since mining depths were mostly over 400 m, exploitation range generally couldn't reach sufficient mining size, even extremely insufficient mining, although which along the strike could. In that case, the height of overburden's failure couldn't reach its maximum in sufficient mining conditions, separation gap was not fully developed, maximum separation space could not be obtained, surface subsidence could not reach its maximum. Therefore, this effect should be taken into consideration when evaluating grouting effect.

Combined with the mining situations in our country, bed separations that were available for grouting had occurred in deep mining, and there were multiple grouting positions that were suitable for grouting according to different geological and mining conditions, but due to the limitation of ability of working faces' management, the lengths of face were limited, sufficient mining conditions was difficult to form along the dip, bed separation zone grouting technique was difficult to be implemented smoothly.

2 RESEARCH ON SUBSIDENCE REDUCING TECHNIQUE BY CONTINUOUSLY FILLING GROUTS INTO STOPE OVERBURDEN BED-SEPARATION ALONG THE DIP

The result of study of dynamic developmental characteristics of overburden bed separation indicated that (Minggao Qian at al. 2003, Jialin Xu & Minggao Qian 2000, Jialin Xu & Minggao Qian. 1998, Jialin Xu et al. 2006, Weibing Zhu et al. 2005), grouts should be injected between fissure zone and bending zone, and present results showed that the division of the "Three-Zone" (Zhiqiang Wang et al. 2011) should base on key stratum theory, so should bed separation subsidence reducing mechanism by grouting. Here raised a subsidence reducing technique by continuously filling grouts into stope overburden bed-separation along the dip, see figure 1.

As shown in figure 1, during producing, section intake airway was arranged along roof of coal seam, return airway was arranged along floor of coal seam, during producing of succeeding face, section intake airway was still arranged along roof of coal seam, return airway was arranged under the gob of last section (Jingli Zhao & Jian Wu 1998), pillar could be totally canceled between faces. According to the conclusion of references 29 and 30, concluded that when adopting arrangement as shown in figure 3, the movement of adjacent working face of overburden strata would form

1-intake airway of last section; 2-return airway of last section; 3-triangular shape coal loss pillar between faces; 4-section intake airway of succeeding face; 5-section return airway of succeeding face

Figure 1. Schematic diagram of completely pillarless overlapping overburden bed-separation zone grouting.

one body, reflected the characteristics of single workface, grouting for overburden bed separation zone shown in the figure had the following characteristics:

(1) Mining was sufficient, filling effect was good. Multiple overlapping faces reflected the characteristics of single workface, when succeeding face was producing, the mining effect on overburden along the dip needed to add up all multiple overlapping faces, the method of determining whether overburden along the dip achieved sufficient mining degree borrowed empirical formula (1) (Yonghai Teng et al. 2009):

$$\Sigma L = (1.2 - 1.4)H_0 \tag{1}$$

Where ΣL, cumulative length of faces along the dip, depended on the number of overlapping faces; H0, the height from face to bed separation positionfor grouting.

The evaluation of grouting effect could depend on formula of elastic thin plate theory(2) (Jinhai Liu et al. 2009):

$$\rho = \frac{k a_m^4 b_m^4}{\pi^4 D(a_m^2 + b_m^2)^2 + k a_m^4 b_m^4} \times 100\% \tag{2}$$

Where k is Winkler foundation coefficient, k = (E0/h0)-2; E0, the elasticity modulus of foundation; h0, cushion thickness; D, flexural rigidity, D = Eh3/12(1-μ2); μ, Poisson's ratio; a_m, b_m were limit sizes of rock plate.

$$a_{m=ab_m/b,}b_m = \sqrt{\frac{[\sigma_t]\delta^2}{6\eta q}} \tag{3}$$

a, b were the length of strike and the length of dip; δ, thickness of rock plate; q, the loads acting on rock plate, q = γδ, γ was unit weight; η was shape

coefficient: $\eta = 0.00302(a/b)3 - 0.03567(a/b)2 + 0.13953(a/b) - 0.05859$

Analyzed formula (1) and (2), the longer the length of face and the more sufficient the mining degree, the better the filling effect you would get. As shown in the figure, the increase of the number of overlapping faces was equivalent to the increase of the length of face along the dip. Obviously, mining of overburden was more sufficient, and filling effect was better in this technique.

(2) Connection between mining influence and grouting was more reasonable, as shown in figure 2, during producing of first face, influenced by mining degree and the distance between the key stratum and the face, volume of initial bed separation was very small, even bed separation would not appear; When the number of overlapping faces increased, bed separation began to develop, before it reached sufficient mining, bed separation was in a development stage, continuous grouting could be achieved through grouting holes, keeping bed separation in development stage for a long time, bed separation was always in cycle of initiation—development—grouting—initiation—development—grouting, grouting continued with the mining degree gradually becoming sufficient, making a better filling effect.

(3) Grouting quantity. The position of water-conducting fractured zone rose with the increase of mining range. Therefore, grouting layer was influenced by mining range, thickness of overburden, bulking property, fracture angle, as shown in figure 1, grouting layer in the system rose, grouting quantity declined.

(4) Drilling work quantity. Continuous bed separation formed as pillars were canceled, and grouting quantity declined, the number of grouting holes along the dip was fewer than that in isolated section-grouting system.

3 EQUIVALENT MATERIALS SIMULATION EXPERIMENT STUDY OF OVERBURDEN BED SEPARATION

Experiment was mainly based on prototype of seams and overburden of a certain coal mine, studied situations of overburden bed separations when adopting completely pillarless overlapping faces in inclined and nearly horizontal coal seams. Two-dimensional test bed was used in this experiment, the size of the test bed was length × width × hei ght = 1620 mm × 160 mm × 1300 mm, adopting plane stress model. Set geometric similarity ratio toαL = 100:1, bulk density ratio to $\alpha\gamma$ = 1.5:1, time ratio to αt = 10. The experiments of nearly horizontal and gradually inclined coal seams were conducted respectively in which advance of face was simulated and bed-separation in overburden developed with it. The key stratum rose with the increase of the advancing distance, and with the strata continuously reaching its limited span, the level of bed separation would rise.

3.1 *Mechanical properties of rock used for simulation*

Measured data of physical and mechanical properties of roof and floor of each layer used for simulation were shown in table 1.

3.2 *Analysis of phenomena of experiment*

The distribution of overburden bed separation and arrangement of grouting holes in inclined coal seam were shown in figure 2.

As shown in figure 2, with the pillar canceled between faces, overburden above the first face would form a integral structure with overburden above the succeeding face, which meant that overlapping faces should be taken into consideration when dividing "Three Zone". Concrete contents had been described in paper "Determination of height of "Three Zone" in the stope with stagger position and internal misaligned roadway layout", here only cited the conclusion because of the limit space of the thesis. As multiple faces reflected the characteristics of single face, the position of fissure zone rose with the increase of the number of succeeding faces, but it was continuous above the stope, therefore, continuous grouting for multiple faces can be achieved. The distribution of overburden bed separation of nearly horizontal coal seams was shown in figure 3.

As shown in figure 3, pillar between sections was canceled, overburden formed a integral structure, multiple faces reflected the characteristics of single face, The position of fissure zone rose, continuous separation zone formed in the upper part of the stope, so grouting can be used for continuous separation zone generated by multiple faces.

2.3 *Conclusions of the experiment*

By contrast of feature of overburden's movement without pillar and that with pillar, the results were as follows:

1. With the pillar canceled between faces, overburden above the first face would form a integral structure with overburden above the succeeding face, The position of fissure zone rose, mining was more sufficient;
2. Due to mining of succeeding face, after determining grouting layers, bed separation was continuous, and with the mining of each

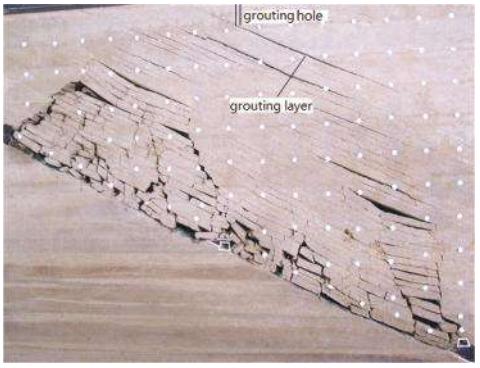

Figure 2. Grouting layer and holes layout completely without pillar in inclined coal seam.

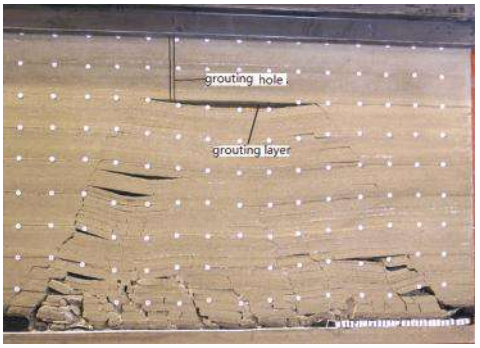

Figure 3. Grouting layer and holes layout completely without pillar in nearly horizontal coal seams condition.

succeeding face, strata below the grouting layer suffered another mining influence, after layout of grouting holes during early stage, with the increase of mining range along the dip and activation of strata below the bed separation for grouting, immediately began to grout when negative pressure appeared at orifice, which meant that grouting work was always performed after activation of strata, subsidence reducing effect was better;

3. Bed separation was continuous in pillarless mining, as a result, efficiency of grouting holes could be made full use of, drilling work quantity was reduced.

4 APPLICATION ANALYSIS

A certain coal mine II_{102} mining district was under village, the length of strike was 2340 m, the length of dip was 700 m, area was 1.6 km^2, the thickness of main mining coal seam was 3 m, average angle was 18°, average depth was 600 m. Ground level was +27 m, the thickness of overburden was 240 m. As the whole mining district had suffered rock magmatic intrusion, igneous rock with huge thickness of 120 m formed 180 m above the coal seam, movement angles of bedrock's rise and dip both were 75°, as shown in figure 4, uniaxial tensile strength of igneous rock was 7.9 MPa, uniaxial compression strength was 96.4 MPa, elastic modulus was 32.4 GPa, Poisson' ratio was 0.256. Determined that first caving span of igneous rock

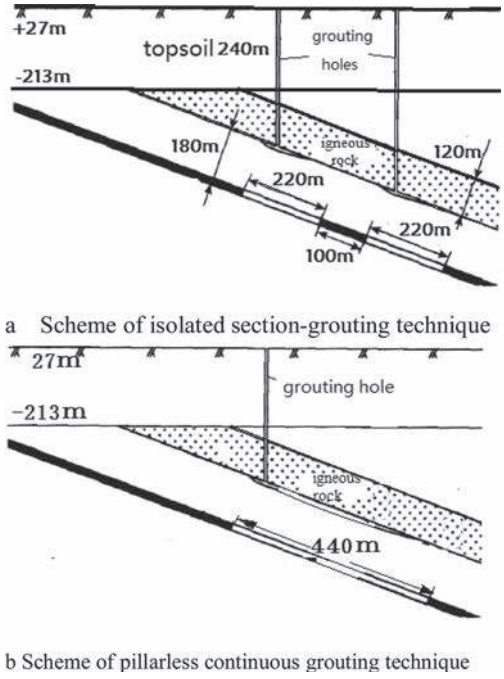

Figure 4. Contrast of schemes of grouting for bed separation.

with huge thickness was 150 m, unidirectional limit size of corresponding face was 245 m.

Isolated section-grouting filling technique was adopted in original scheme. First, determined to adopt 200-meter-long longwall working face for stopping, as shown in figure 4(a), in order to prevent isolated separations below the key stratum from connecting, the width of pillar to be remained was greater than 96.46 m, adopted 100 m. Used combination of 2-millimeter-long refuse and fly ash as aggregate in grouting system, it was carried by water to bed separation of igneous rock with huge thickness through ground drilling holes, water was discharged through drainage holes continuously, and that cycle repeated, until separation was fully filled with refuse and fly ash.

First made judgements about the mining degree and filling effect, with the calculation of formula, found that overburden was in critical state of sufficient mining during producing of single face, subsidence reducing rate was 57%.

What's more, the length of face was 220 m, the length of pillar left was 100 m, after two adjacent sections were mined out, there was still about 140-meter-long coal seam could not be mined, resulting in a waste of about 220-meter-long coal seam.

In order to improving current situation of grouting technique, raised a scheme of completely pillarless continuous grouting technique for the coal mine, as shown in figure 4(b). By calculating, overburden was in insufficient mining stage during producing of succeeding face, subsidence reducing rate was 85.6%.

In the meantime, the length of face was 220 m, after three overlapping face formed, protective coal pillars were preserved for mining district on the border of mining district, thus realized fully recovery of resource of the coal mine. In comparison with the original design, taking advancing distance of the mining district into consideration, nearly 1.74 Mt coal resource can be recycled.

In addition, compared (a) with (b) in figure 4, as grouting holes were arranged over first face, and grouting had begun during producing of first face, after activation of strata and mining influence when succeeding face was producing, immediately began to grout when negative pressure appeared at orifice, could effectively support igneous rock, compared with original scheme, subsidence reducing rate and recovery increased while also quantity of drilling was reduced.

5 CONCLUSION

The study was conducted based on grouting for overburden bed-separation along the dip. Proposed subsidence reducing technique by continuously filling grouts into stope overburden bed-separation along the dip. The biggest difference was that pillar between faces was canceled completely. By theoretical and experimental analysis, concluded that the technology had a feature that the mining degree was higher, the connection of grouting and mining was more reasonable, and on the premise of relatively small quantity of grouting and grouting drilling works, achieved relatively ideal subsidence reducing effect. In the end, this technology was verified based on practical engineering context, considered that the technology had a feature that the mining degree was higher, grouting effect was more evident, mining district arrangement was more reasonable and drilling works quantity reduced and so on. Therefore, considered that this technology had a certain promotional value.

Optimization of roadway layout and its effect analysis for lower protective seam in fully mechanized caving mining

Zhongbao Chang
Xishan Coal Eelectricity Group Company, Taiyuan, China

Qingbo Hui, Yutong Li, Zhiqiang Wang & Jingli Zhao
School of Resource and Safety Engineering, China University of Mining and Technology, Beijing, China

ABSTRACT: The research was conducted based on lower protective seam mining. Practice showed that adopting super-long fully-mechanized caving face for lower protective seam mining has problems of large volume of gas emission, relatively low yield of face, large engineering quantity of roadway and limited released range, etc. In the study, first through measured data obtained parameters of range of overlying coal seams that lower protective seam released. On this basis proposed a technical optimization measures and obtained a series of effects, including: If arranged completely pillarless working faces overlapping each other in protective layer, the adjacent face could increase pressure-released area of No. 1 coal seam by 99,200 square meters compared to the original method. After changing original "U + I" ventilation mode of the protective layer's first mining face to "Y+L" mode, succeeding working face could save engineering quantity by 3238 m. On the basis of increased recovery rate and reduced quantity of roadway engineering, after the optimization, economic benefit could be increased by 95.037 million yuan compared with the original scheme. Combined with daily output, advancing speed and their effect on gas emission, adjusted the length of the original super-long fully-mechanized caving face to 125 m, advanced 4.2 m per day. Finally, tested the releasing effect of protective seam face in fully mechanized caving mining, and considered that overlying coal seam was in full-pressure-released state, proved that optimized measure was reasonable.

1 INTRODUCTION

Coal seams in our country generally have characteristics of high metamorphic grade, low pressure, low permeability and low gas bearing saturation (Jianping Ye et al. 1999, Shining Zhou et al. 2001). Coal Seam mining can cause movement of rock, break as well as "Pressure relief anti reflective" effect of surrounding rock, which means that coal seam permeability will increase from tens to hundreds of times, and that creates conditions for further extraction of gas (Qixiang Yu 1992, Jialin Xu et al. 2004, Minggao Qian et al. 2003, Qianting Hu et al. 2000, Qixiang Yu et al. 2004, Minggao Qian et al. 2003, Jialin Xu & Minggao Qian 2000). In the study of pressure-relief effect of coal mining on overlying coal and rock strata (Xueqiu He et al. 2006), got the following conclusions: when mining depths were the same, effective pressure-relief height was proportional to the length of the working face. For a long time, research had been focused on the pressure releasing effect of the protected seam, ignored that when the length of protective layer mining face was increased, the gas emission would increase, and generated problems of related face's high production and high efficiency and large engineering quantity of roadway, especially in fully-mechanized caving mining face.

The practice also has shown that although the Xinglong Coal mine, Lu'an Wangzhuang mine have successfully applied nearly 300-meter-long experimental mechanized caving face (Shenggen Cao & Xiexing Miao 2001, Bin Ding et al. 2005, Zhiqing Zhao & Yue Zhang 2005), due to threat of gas, face production capacity was difficult to make a further increase (Baozhong Yang 2004).

In summary, on the basis of pressure relief in super-long fully-mechanized caving face in protective layer, for problems that existed in super-long fully-mechanized caving face such as large gas emission, relatively low yield, large roadway projects and the limited releasing range, conducted a research, optimized the corresponding technical measures as well as technique parameters, and the destressing effects were finally validated.

2 ENGINEERING CONTEXT

A certain mine are mainly mining two coal layers, average thickness of the upper coal seam 1# is 1.81 m, its original gas content is 32.41 m^3/t, gas pressure is up to 1.3 Mpa, permeability coefficient of the coal seam is only 0.00037 m/(MPa2.d), belongs to hard drainable coal seam. In production practice, there have been several coal and gas outbursts, which seriously affected production. Average thickness of coal 2# 138.5 meters below the coal 1# is 6.7 m, original gas content is 7.13 M^3/t, gas pressure is 0.2–0.3 MPa, belongs to low-gas coal, average dip angle is 5°.

The mine mined coal 1# in early stage, the length of working face designed was 150 m. Coal and gas outburst happened 30 times during tunneling of return-air roadway and exterior alternate tail roadway, face's advance was less than 100 m when it was forced to halt due to coal and gas outbursts, but fresh air supply was continued for working face, air volume was 660 m^3/min, return air volume was 420 m^3/min, gas concentration was 0.22%; air volume of alternate exterior tail roadway was 240 m^3/min, gas concentration ranged from 0.6% to 0.7%. In order to achieve safe mining of coal 1#, pre-pressure relief and gas extraction were needed, so designed to pre-mine coal 2# as a protective layer which was below coal 1#. Due to the large distance between the two coal beds, research was needed to conduct to determine whether the coal 2# had the function of protective layer. Arranged 250-meter-long fully-mechanized caving face within coal 2#, and the layout orientation of face of upper and lower coal seams were shown as figure 1.

As shown in Figure 1, the protective layer mining face used "U + I" ventilation mode while the protected seam used "U+L" mode. In order to grasp mining effect of coal 2# on destressing effect of coal 1#, measured parameters at the same time. First, obtained parameter changes of gas from protected layer during the producing of protective layer's face, and use it as judge foundation for distressing border along the strike of protected layer. Then during the advancing and producing of protected seam face, obtained parameter changes of gas and used it as distressing border along the dip of protected layer's face.

When coal 2# working face advanced 16 m near alternate exterior tail roadway of coal 1# working face, gas concentration in return airway and tail roadway of coal 1# face was increased to 1.9% and 2.2% respectively. pre-extracted gas in protected seam working face due to serious overranging gas concentration in coal 1# working face with the advancing of coal 2# working face.

From the measured data know that gas gushed out because of the distressing effect on coal 1#. Amount of ventilation air methane increased from 2.6 m^3/min to 13.6 m^3/min before gas extraction; In the range from the beginning of extracting to 110 m past tail roadway coal 2# advanced, the distribution range of the extractable pressure relief gas expanded and the extraction volume increased, and extraction volume increased from 7.2 m^3/min to 27.2 m^3/min. Coal 2# face continued to advance, and during the stage that coal face reached intake airflow roadway of coal 1# and advance 72 m, the extraction volume was always maintained 27 m^3/min on average. After that, the concentration of extractable pressure-relief gas reduced, and reasons were thought to be the re-compaction of coal 1# face, and began to stabilize.

In order to further obtain the released range of coal 2# face along the dip, resume production of coal 1# face while volume of gas extraction of coal 1# face was always maintained at an approximate setting value (the measured data was 11.2 m^3/min), so that determined the released range of the coal 2# along the dip by the measured data of ventilation air methane per ton. Before the coal 1# face advanced 30 m past return airflow roadway of coal 2# face, the range of face ventilation air methane per ton was 11.3~157.8 m^3/t; When the coal 1# face advanced 30 m to 240 m past return airflow roadway of coal 2# face, ventilation air methane per ton reduced to 8.9 m^3/t from 34.4 m^3/t; After advanced 240 m, ventilation air methane per ton rose again, up to 45 m^3/t, 22.3 M^3/t on average.

According to measured data, got the destressing parameters of coal 1# when mining coal 2# in fully-mechanized caving, as shown in figure 2.

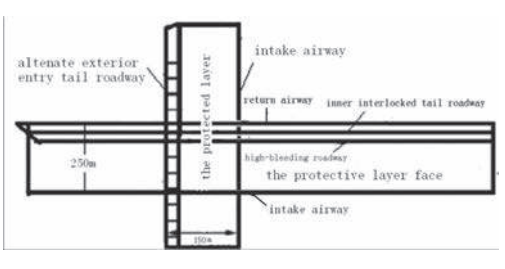

Figure 1. Schematic diagram of faces' layout of the upper and lower coal seams.

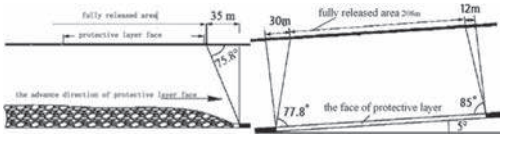

Figure 2. Destressing situation of coal 2# mining for coal 1#.

As can be seen from figure 2, during advancing of the coal 2# face along the strike, coal 1# face began to be in fully distressed area about 35 m behind the coal 2# face, the corresponding pressure-relief angle was 75.8 °. Along the dip of the working face of coal 2#, coal 1# obtained pressure relief from 12 m inner side of the upper end to the 30 m inner side of the lower end. corresponding pressure relief angle were 77.8 ° and 85 °.

3 PROBLEMS

3.1 *Gas emission of working face was large*

During mining of super-long fully-mechanized caving face, due to large thickness, gas emission were large, mainly including gas from coal wall, gas from dropped coal, gas from drawing coal, gas from goaf. Goaf gas came from residual coal in goaf and the released overlying coal. In order to effectively discharge gas and realize safe production, designed alternate interior tail roadway, rear high level suction roadway, high level suction roadway along the. See in figure 3.

Processed data of the super-long fully-mechanized caving face of coal 2# in different mining period, found the following characteristics:

1. Air supply amount of coal 2# super-long fully-mechanized caving face during the early mining period was 2463 m³/min, advanced 2.6 m per day, daily output was 5974 t, did not achieve the anticipated goal of high production and high efficiency of super-long fully-mechanized caving face.
2. After normal stopping, face daily advance distance was 3.35 m, daily output was up to 8699 t, ventilation air methane was 26.9 m³/min, and during the mining process, gas concentration of upper corner in fully-mechanized caving face sometimes exceeded limit.

In summary, super-long fully-mechanized caving face was used for mining as a protective layer, its high productivity and high efficiency advantages were not fully reflected, and the large amount of gas emission threatened the safety of face production.

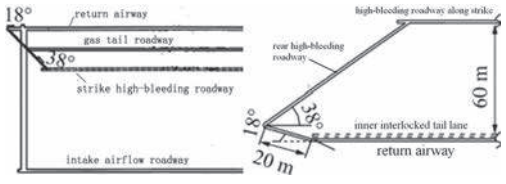

Figure 3. Gas drainage measures of coal 2# super-long fully-mechanized caving face.

2.2 *Large quantity of roadway engineering*

As shown in figure 3, in order to ensure the safe production of coal 2# face, arranged gas tail roadway, strike high level suction roadway, rear high level suction roadway. In accordance with the designed advance distance, the lengths of these roadways were 1600 m, 1530 m and 108 m respectively. It could be seen that the roadway workload of super-long fully-mechanized caving face was very large, increased mine production costs, reduced production efficiency.

As coal 2# belonged to the super-long fully-mechanized caving face, at least 20 m wide coal pillar must be remained between faces. According to the measured destressing parameters, at least a scope of 62 m between two faces along the dip would be in unprotected areas, and affected by coal pillar of protective layer face, unprotected areas of coal 1# belonged to high stress distribution areas. Therefore, riskiness of coal and gas outburst of coal 1# was increased during the mining process.

4 TECHNICAL MEASURES OPTIMIZATION OF PROTECTIVE LAYER FACE

4.1 *Optimization of roadway layout*

In order to achieve the fully pressure-relief of protected layer and reduce the amount of roadway engineering of protective layer, optimized the face layout of protective layer, that is, adopted layout of working face overlapping each other completely without coal pillar between two faces (Jingli Zhao & Jian Wu 2002), as shown in Figure 4.

As shown in Figure 4, arranged the succeeding face's return air roadway below the last face's goaf, during producing of the succeeding face, the overlying strata of the two working face moved, forming a whole, reflected the characteristics of a single face (Zhiqiang Wang 2009). With this feature, used this roadway layout in coal 2# and improved some problems existed in original roadway layout. Including:

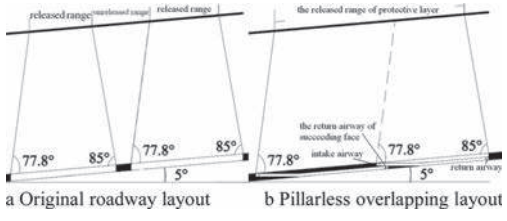

Figure 4. Pressure-relief effect contrast of coal 1# before and after roadway layout optimization.

1 The pressure relief range

As shown in figure 4 was the original layout scheme, since coal pillars existed between super-long mechanized caving face of protective layer, destressed zone and undestressed zone alternately appeared in coal 1#. From the face layout of two seams, saw that this would greatly influence the coal 1#'s face advancing. Figure 4 (b) showed pressure relief situation of coal 1# destressed by working face overlapping each other completely without coal pillar, if a single face was mining, there were no differences with original roadway layout, that is, a pressure relief border existed from both sides towards coal 1#, But after succeeding face was formed, due to the particularity of internal misaligned arrangement, the pressure relief boundary lines at lower end of original face disappeared, only existed on both sides of succeeding face. Thus forming a continuous distressing range in the protected layer, and compared to original roadway layout, adjacent two faces could increase pressure relief range of coal 1# by 99, 200 square meters which brought a positive effect for the safe mining of coal 1#.

2 The amount of roadway engineering

As shown in figure 5, after roadway's optimization, made full use of coal seam's dip and face's overlapping relationship, remained the return airway, tail roadway and the strike high level suction roadwayof the first mining face, Used stope space "O"-ring theory (Minggao Qian & Jialin Xu 1998), after forming internal misaligned overlapping in succeeding face, changed the face's original "U + I" ventilation mode to "Y+L" mode, that is, two roadways of succeeding face were all for air intake, polluted air was discharged through return airway of the first face.

Compared the amount of roadway engineering, due to starting saving excavation of gas tail roadway, strike high level suction roadway and the rear high level suction roadway from succeeding working face, a single working face can save the amount of mine engineering 3238 m.

Figure 5. The arrangement of coal 2# face after optimization of roadway.

3 Technical and economic comparison

What was shown in Figure 6 was overlapping part of face completely without coal pillar. Calculating according to1600 m advance distance of the face, the loss of coal was 114,800 t. If according to design, preset 20 m coal pillar between two faces, the coal loss was 415,400 t. As could be seen, used overlapping completely without pillar, coal resource could be recovered 300,600 t. The economic comparison of optimization technical measures with original program was shown in table 1:

In fact, the table did not reflect the economic evaluation of the pressure relief range after the optimization of technology. Because there is not yet accounting the security investment of protective layer, so temporarily ignore it. However, it can be seen from the table, only consider addition of the recovery rate, the reduction of the roadway excavation and maintenance costs, the optimized technical measures added value of 95.037 million yuan than the original program. Thus, the economy of optimized technical solutions is objective.

4.2 *The optimization of process parameters*

4.2.1 *Working face production effects on gas emission*

Studies showed that production of working face had a greater influence on volume of gas emission, literature (Zhijun Du 2006, Guanglong Dai & Fangjian Chu 2005, Shaolin Lv 1997) indicated that face production wasn't proportional to volume of gas emission. Through analysis, got the

1-Intake airway of the last section; 2-Return airway of the followed face.

Figure 6. Triangle coal loss of working face overlapping each other completely without coal pillar.

Table 1. Economic benefits after technical optimization.

Evaluation index	Total	Gross (ten thousand yuan)
Recovery economy	+300600 t	+9018
Roadway excavation and support	–3238 m	–4857
Total	9503.7 yuan	

Note: + – in table represented the increased economic efficiency and reduced cost respectively. Unit benefit of coal mining was calculated in term of 300 yuan, the drivage and support cost of roadway take 1500/m.

relationship between production of super-long fully-mechanized caving face and volume of ventilation air methane, as shown in figure 7.

The measured data showed that when face production was less than 8000t, the addition of face gas emission approximate linearly increase with the increasing of production capacity; when face production is 8000t-12000t, the gas emission remains in the 26–27 m ³/min, when face production was greater than 12000t, gas emission was in a downward trend with the increase of production.

As shown in the figure, the relationship between amount of ventilation air methane and face production capacity is in negative exponential trend, and the calculation formula is:

$$Q = 10.424te^{(-0.0001t)}$$

3.2.2 *Advance speed influence on volume of gas emission of adjacent layer*

Through calculation of length and advance speed of protective layer face, daily pressure relief area in protective layer could be obtained. During the normal production of the protective layer, measured data of gas emission of adjacent layer and processed data by using liner regression.

As shown in figure 8, face advance speed and volume of gas emission of protection layers exist obvious exponential relationship, and they satisfy the relation:

$$q = 104.08ve^{-0.234v}$$

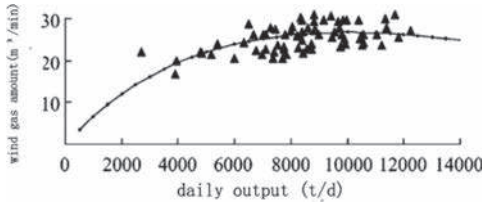

Figure 7. Relationship between super-long fully-mechanized caving face's daily output and volume of gas emission.

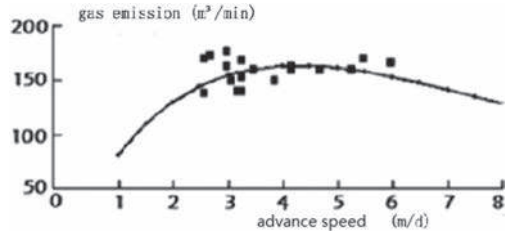

Figure 8. Relationship between face advance speed and volume of gas emission.

Analyzed the formula, and thought that when face advance speed was less than 3.5 m/s, volume of gas emission of protected layer was proportional to face advance speed; When face advance speed was between 3.5~5.5 m/s, volume of gas emission of pressure relief layer mainly remained at 160 to 163 m³/min; When advance speed was greater than 5.5 m, volume of gas emission of pressure relief layer had a downward trend.

In summary, synthesized factors of the optimization measures of roadway layout, volume of gas emission of protected layer and the large amount of gas emission of super-long mechanized face, determine that the length of the face was 125 m, in coal for the, daily cut was 7, the cumulative advance distance was 4.2 m after optimization of roadway layout in coal 2#.

5 EXAMINATION OF DESTRESSING EFFECT AFTER TECHNICAL OPTIMIZATION

In order to ameliorate the problems of lower relative yield and large volume of gas emission existed in original designed super-long fully-mechanized caving face. Optimized the original face length to 125 m, so pressure relief effect of coal 1# caused by the mining of optimized coal 2# needed to be verified. Established numerical simulation model of UDEC^{2D}, according to the actual situation, set the length and width of the model to 544 m and 236 m, added uniform loading of 9 MPa above the model, and left 150 m protective coal pillar at the two boundaries of the model. The focus of the analysis was the pressure relief effect on the protected layer when succeeding face was producing. Due to use of face overlapping each other completely without coal pillar, so triangle coal loss would be left between succeeding face and the first mining face.

The specific physical and mechanical properties of coal and rock were shown in table 2.

Through processed data calculated, obtained the deformation and the vertical stress changes of protected layer when succeeding face was producing, as shown in figure 10.

As shown in figure 10, the effect of coal 2# adopting face overlapping each other completely without coal pillar on protective layer of coal 1# was in area of 75 m away outside the face. And the maximum compression ratio was 0.15%, the maximum stress concentration coefficient was approximately 1.2; Protected layer was released by expansion within the range 5 ~ 75 m of inner side of the protective layer face; the expansion ratio was approximately 0.8%, the stress was about 9% of stress in virgin rock mass. Expansion releasing state of the protected layer in the middle of the two

Table 2. The table of physical and mechanical parameters of coal rock.

Strata	Siltstone	Gritstone	Fine sandstone	Medium sandstone	Coal	Mudstone	Sandy mudstone
Elastic Modulus/GPa	20.2	25	15	35	2.2	2	1.5
Tensile Strength/ MPa	1.3	1.4	1.5	1.5	1	1.2	1.3
Normal stiffness/ $GN \cdot m^{-1}$	16	18	21	20	5	9.6	7.5
shear stiffness/ $GN \cdot m^{-1}$	12	14	16	16	3.5	6.2	4.5
Poisson ratio	0.19	0.19	0.2	0.15	0.28	0.24	0.26

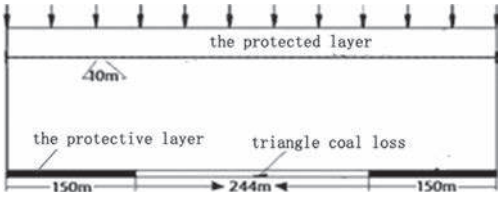

Figure 9. Experimental model.

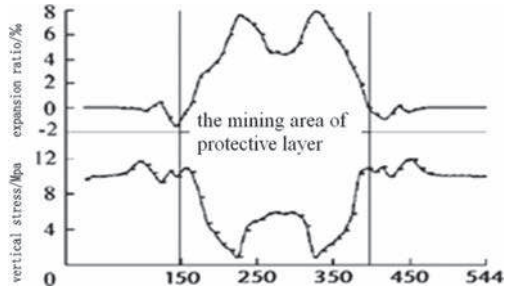

Figure 10. Mining effect of coal 2# completely without coal pillar on deformation and stress of coal 1#.

faces has been restored to some extent; the expansion rate was stable at 0.4%, and the maximum stress recovered to 60.4% of stress in virgin rock mass. Considered through analysis that because of triangle coal loss between two faces, so here was easy to be stable and compacted. More than 3 ‰ of protected layer on both ends of the protected layer was within 195 m range 33 m and 16 m staggered with protective layer face. Showed here was in the state of full pressure relief, and the pressure discharging angles were 77.6 ° and 83.4 °.

6 CONCLUSION

Theory and practice showed that mining using super-long fully-mechanized caving face as lower protective layer had problems of large gas emission, large amount of roadway workload, difficult to achieve high yield and high efficiency of face, and the pressure relief range was limited, etc. On this basis further proposed technical optimization, achievements included: the adjacent face could increase pressure-released area of coal 1# by 99,200 square meters compared to the original method if arranged completely pillarless working faces overlapping each other in protective layer. After changing original "U + I" ventilation mode of the protective layer's first mining face to "Y+L" mode, succeeding working face could save by 3238 m. Compared with the original scheme, after the optimization, economic benefit could be increased by 95.037 million yuan. Combined with daily output, advance speed and their effect on gas emission, adjusted the length of the original super-long fully-mechanized caving face to 125 m, advanced 4.2 m per day.

Safety evaluation model and application for purification device of sour natural gas based on risk

Jun Yi, Meng Zong & Wen-He Wang
Chongqing University of Science and Technology, Chongqing, China

ABSTRACT: By analyzing the hierarchy of safety factors in purification plant of natural gas, they are divided into personnel, equipment, environment and management. After the study of safety index, evaluation methods and fuzzy arithmetic method for each hierarchy, its fuzzy evaluation flow is given. During the evaluation, the weight of the factors and each hierarchy is decided by analytical hierarchical process, and the operational criterion adapts maximum membership degree. And this model is exemplified in purification plant of natural gas. The results show that the second fuzzy evaluation is effective to assess purification plant of natural gas.

1 INTRODUCTION

The security operation of natural gas purification plant relates to the factory and the safety of operators, for there exists flammable, explosive gas in it. Once incidents come out, it will cause casualties and economic loss (CAI & YAO 2008, PENG et al 2009, SHAO et al 2007). Because of the complex production environment of natural gas purification plant, factors causing the risk in the plant are various, most of which are fuzzy. Therefore, adopting the fuzzy comprehensive evaluation model can analyze the possibilities and consequences of all kinds of risks. Using fuzzy language can express the possibilities and consequences of the risks in the plant, and determine the sort of the risk area, so as to guide the safe production (HUANG & J1 ANG 2007).

2 THE CONSTRUCTION OF SAFETY EVALUATION MODEL

2.1 *The construction of evaluation model*

1. The construction of the factors set of evaluation object
   In this article, the evaluation object factors set expressed by U are all factors that cause the danger of the plant. Assume the evaluation factors that influence the final evaluation results of the evaluation object are u_1 u_2 … u_n. Thus, the factors set can be expressed as:

$$U = (u_i)\ i = 1,2\ldots,n \tag{1}$$

   Each factor can be divided into M number of influencing factors, and the grand set can be expressed as:

$$u_i = (u_{i1} \quad u_{i2} \quad \ldots \quad u_{im})\ i = 1,2,\ldots,n \tag{2}$$

2. The determination of the weight coefficient
   In addition to confirm the factors set of evaluation object and each factor's subset, their weights also need to be determined. Factorial weighting set reflects each factor's influence on evaluation object. It can be expressed as:

$$A = (a_i)\ i = 1,2,\ldots,n. \tag{3}$$

   The a_i must satisfy the normalization condition:

$$\sum_{i=1}^{n} a_i = 1, \tag{4}$$

   A corresponding weighting set is constructed in light of each factor in the factors set, which can be expressed as:

$$A_i = (a_{i1} \quad a_{i2} \quad \ldots \quad a_{im})\ i = 1,2,\ldots,n \tag{5}$$

3. The construction of the alternative set
   The alternative set consists of the overall evaluation results that the valuators made on evaluation object. Generally speaking, the assessment of value range and the degree of language are taken as the evaluation object. The alternative set usually can be expressed as:

$$V = (v_1 \quad v_2 \quad \cdots \quad v_k) \tag{6}$$

Assume the alternative sets are divided into 5 grades. It can be expressed by fuzzy language as:

$$V = (\textit{safest safe general dangerous most dangerous}) \tag{7}$$

2.2 *Class A fuzzy comprehensive evaluation*

Class A fuzzy comprehensive evaluation method is also called single factor fuzzy comprehensive evaluation method. It makes evaluation on a single factor through synthesizing the contribution that each grand of one factor makes to the value of evaluation objects (PENG 2002, PENG et al. 2012). Membership function matrix of each factor level is shown as follows:

$$R = \begin{pmatrix} r_{i11} & r_{i12} & \cdots & r_{i1k} \\ r_{i21} & r_{i22} & \cdots & r_{i2k} \\ \vdots & \vdots & \vdots & \vdots \\ r_{in1} & r_{in2} & \cdots & r_{ink} \end{pmatrix} \quad i = 1,2\ldots,n \tag{8}$$

$$B_i = A_i \bullet R_i = \begin{pmatrix} a_{i1} & a_{i2} & a_{i3} & a_{i4} \end{pmatrix} \bullet \begin{pmatrix} r_{i11} & r_{i12} & \cdots & r_{i1k} \\ r_{i21} & r_{i22} & \cdots & r_{i2k} \\ \vdots & \vdots & \vdots & \vdots \\ r_{in1} & r_{in2} & \cdots & r_{ink} \end{pmatrix} \tag{9}$$

The corresponding rank weights are constructed with regard to each factor

$$A_i = \begin{pmatrix} a_{i1} & a_{i2} & a_{i3} & a_{i4} \end{pmatrix} \tag{10}$$

Therefore, class A fuzzy comprehensive evaluation matrix is shown as:

$$R = \begin{pmatrix} A_1 \bullet R_1 \\ A_2 \bullet R_2 \\ \vdots \\ A_n \bullet R_n \end{pmatrix} i = 1,2,\cdots,n \tag{11}$$

$$B = A \bullet R = \begin{pmatrix} b_1, & b_2, & \cdots & b_k \end{pmatrix} \tag{12}$$

2.3 *Secondary fuzzy comprehensive evaluation*

Class A fuzzy comprehensive evaluation just considers the influence of single factor on the evaluation objects but ignores the relation of various factors. Now the risk level of evaluation objects is calculated after the weight of each factor is given (PENG 2002, PENG et al. 2012, TAN et al. 2012, XIN & WANG 2012). The result of fuzzy comprehensive evaluation comes out according to the overall merit of all influencing factors.

$$C = A \circ B = \begin{pmatrix} c_1 & c_2 & \ldots & c_k \end{pmatrix} \tag{13}$$

After normalization, the synthesis appraisal result vector is shown as:

$$C' = \begin{pmatrix} c_1', & c_2', & \ldots & c_k' \end{pmatrix} \tag{14}$$

Adopting the maximum membership degree principle of judgment, safety grade belongs to:

$$r_{i\max} \left(i = 1,2\ldots,m\right) \tag{15}$$

3 PROJECT CASES

3.1 *The construction of evaluation model*

The Security incidents of purification plant are influenced by many factors. However, each factor can just reflect one side of the problem. In order to evaluate the safety level of the purification plant comprehensively, it is necessary to introduce indicators as much as possible in the evaluation model and follow an independent, comprehensive, comparable principle at the same time (SHENG et al. 2012, ZHOU et al. 2012). So this paper uses the Analytic Hierarchy Process (AHP) analysis and forms well-organized recursive node hierarchy structure, as shown in Figure 1.

3.2 *The confirmation of the result of evaluation matrix*

On the basis of investigation and research, in accordance with the method of fuzzy evaluation and the different grades of membership of each factor given through the expert scoring, it is easy to obtain the first-order evaluation matrix. Then the comprehensive evaluation matrix is obtained

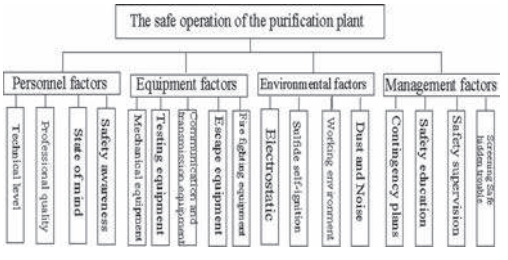

Figure 1. The security hierarchy structure of Purification plant security hierarchy.

Table 1. Fuzzy evaluation results.

evaluation factors			evaluation subfactors				Evaluation situation					$B_i = A_i \circ R_i$	normalization results

			V_{32}	Sulfide self-ignition	0.15									
			V_{33}	Working environment	0.21									
			V_{34}	dust and noise	0.18									
V_4	Management factors	0.41	V_{41}	Contingency plans	0.24	$A_4=(0.24\ \ 0.1\ \ 0.25\ \ 0.41)$	R_4	$\begin{pmatrix}0.5&0.2&0.2&0.1&0\\0.3&0.3&0.2&0.2&0\\0.3&0.4&0.2&0.1&0\\0.3&0.3&0.2&0.1&0.1\end{pmatrix}$					$B_4=A_4\circ R_4$ $=(0.3\ \ 0.3\ \ 0.2\ \ 0.1\ \ 0.1)$	$(0.3\ \ 0.3\ \ 0.2\ \ 0.1\ \ 0.1)$
			V_{42}	Safety education	0.1									
			V_{43}	Safety supervision	0.25									
			V_{44}	screening Safe hidden trouble	0.41									

by allocating and compounding the matrix with corresponding weights of factors. The evaluation results are shown in Table 1.

Obtaining the evaluation matrix from Table 1

$$R=\begin{pmatrix}B_1\\B_2\\B_3\\B_4\end{pmatrix}=\begin{pmatrix}0.25&0.417&0.167&0.083&0.083\\0.273&0.273&0.182&0.182&0.091\\0.2&0.2&0.4&0.1&0.1\\0.3&0.3&0.2&0.1&0.1\end{pmatrix}$$

So the comprehensive fuzzy evaluation matrix is $B' = V \cdot R$ and it is calculated as: $B = (0.3\ \ 0.3\ \ 0.2\ \ 0.182\ \ 0.1)$.

After normalization, it gets $B = (0.277\ \ 0.277\ \ 0.185\ \ 0.168\ \ 0.092)$.

It can judge that the criticality of the plant is "safer" above level by combining the result and maximum membership principle.

4 CONCLUSION

1. Because there exist many risk factors in natural gas purification plant and each factor is complex, it is difficult to form safety evaluation model reasonably with the classical mathematics method, while the membership function in fuzzy mathematics and fuzzy comprehensive evaluation theory can better assess the safety of purification plant.
2. Use expert scoring method to determine the weight of each factor. Therefore, the selection of experts must be extensive, including not only first-line production workers, but also middle supervisors and senior coordinators. This result has universality, for it is discussed in reasonable personnel structure.
3. The overall security situation of the plant is "safer" above level. During calculating it has been found that the proportion of environmental factor is only 0.1. But the fuzzy operation results show that the security situation in the "general" level. Therefore, environmental factors are relatively weak, especially the electrostatic influence. And it is necessary to strengthen the supervision.

Coal mine comprehensive safety information management system based on the cloud computing

Shuang-Yue Liu & Tian-Yu Xiong
Civil and Environmental Engineering School, University of Science and Technology Beijing, Beijing, China

ABSTRACT: A Coal Mine Comprehensive Safety Information Management System based on the cloud computing platform which aims at the current shortcomings in the safety of the domestic coal industry management information system were proposed. The system is based on the blue cloud computing platform, integrated coal mine data monitoring, hazard protection and quality assessment of three major subsystems. The introduction of a distributed processing model, aims to integrate existing information platforms solving the problem of heavy hardware construction, light software investments and negligence of service. The goal of scheme is to achieve a smooth transition from the existing information management system and form a set of the integrated cluster security management program.

Keywords: cloud computing, mine safety, safety management

1 INTRODUCTION

The integration of distributed information management system is the development trend of coal mine safety information management in the future. The so-called cloud computing, is relying on the Internet as a service approach, based on the specific needs of computers and related equipment to provide hardware-level-share software resources. With the resources of interconnected networks constructed based pool of computing resources, and the implementation of unified management, according to the actual needs of users to provide services, the emergence of cloud computing technology provides a new way of thinking for research and development of a new generation of distributed Mine Safety Information System (Liu et al. 2012).

2 MINE INFORMATIZATION DEVELOPMENT STATUS AND PROBLEMS

- Uneven development of information technology Although China's coal-mining industry information on the application of information technology has made a certain progress, but low level of development companies and many SMEs, due to lack of funds, technical weakness, lack of awareness and backward management and other reasons, are still in its infancy of the process of information technology (Ma et al. 2010).
- "Information island" restricting the flow of information.

  With the development of information technology, communications and data sharing has become a pressing need. In tradition coal mine enterprise informatization construction lack of unified norms and standards, different mining area in the same item of information management with several subsystems, which lack of the necessary information sharing between systems and equipment, and in a state of "information island" (Zhu & Qi 2012).
- Attaches great importance to the hardware despise software, ignore the service.

  Investigation shows that the coal enterprise information for more focused on the hardware. By 2010, coal mining industry in the aspect of network construction showed that degree of network coverage in more than 90%, large coal mining enterprises network bandwidth in lG more than 70%, computer Internet access rates in more than 90% of companies have over half. But it should be pointed out that, when a lot of coal mines focus on hardware investment in the information construction, they ignore the internal information resources development.

3 CLOUD COMPUTING AND RELATED TECHNOLOGIES

Cloud computing is not a new concept in nature (Leavitt 2009, MELLPP & GRANCE 2011).

As early as in 1961, computing pioneer John McCarthy predicted: "the future of the computing resources can like public facilities (such as water, electricity) is used." (FOSTER et al. 2008) According to the national institute of standards and technology, the core of the cloud computing is to use the network computing resources unified management and scheduling, to constitute a computational resources pool on demand service to users. Providing resources network is known as the "cloud", and service is the nature of cloud (Boss et al. 2007). For this reason, information management system based on cloud computing platform has removed a large number of hardware devices upfront costs troubles (MILOJICIC et al. 2011).

3.1 *The core services of the cloud computing*

Cloud computing core services usually can be divided into three sub layers: Infrastructure as a Service (IaaS), Platform as a Service (PaaS), Software as a Service (SaaS) (WANG et al. 2008). Three sub layers of the relationship can be represented in Figure 1. IaaS provides hardware infrastructure deployment services, demand for the user to provide physical and virtual resources such as computing, storage, and network. PaaS is cloud computing applications running environment, provide the application deployment and management services. With PaaS layer software tools and development language, application developers need to upload the program code and data can use the service, rather than having to focus on the underlying network, storage, management of the operating system problems. SaaS is based on cloud computing platform developed by the application. Enterprise can through rent the SaaS service to solve the problem of enterprise information.

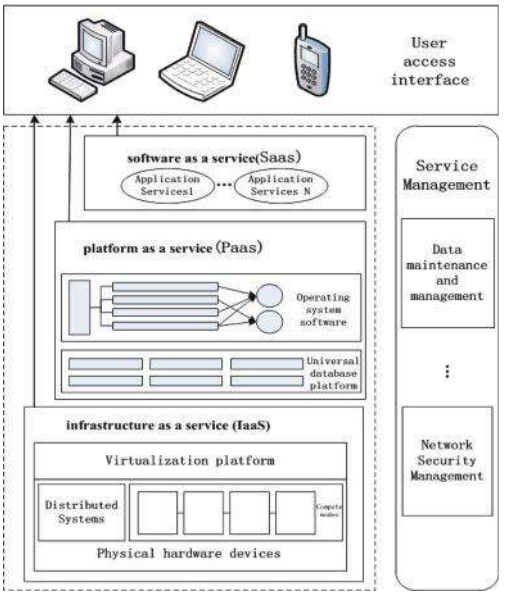

Figure 1. The core service structure of cloud computing.

3.2 *The IBM cloud computing platform*

Currently, Amazon, Google, IBM, Microsoft, Sun, etc., have proposed the cloud computing infrastructure or cloud computing platform (Barroso et al. 2003). "Blue Cloud" infrastructure based on IBM's Almaden research center, used the Xen and PowerVM virtualization software (IBM 2009), Linux operating system images and Hadoop software (Apache 2010). (The Google File System and open source implementations of MapReduce). Compared with the existing network model, the advantages of "Blue Cloud" platform are shown in Table 1.

The important feature of "Blue Cloud" software is the use of virtualization technology (Smith & Nair 2005). Virtualization in "Blue Cloud" has two levels, one is in the level of hardware virtualization, and the other one is by open source virtualization software. Hardware level of server virtuali-

Table 1. "Blue Cloud" computing platform comparison with existing platforms.

	The "Blue Cloud" computing model	Existing models
Application resource allocation	Distribution of virtual resources to applications from the uniform resource pools	Purchase the server for each application deployment server alone
Application runtime environment	Virtualization environment	Physical machine
Application expansion	From the resource pool to increase resources for the application	Purchase of a new server for the application
Application Monitoring	System forms an overall application monitoring system	For each application deployed a monitoring system
OS application deployment and upgrades	Complete automation through self-service interface	Manually
Resource utilization	High	Low

zation can use IBM P series, obtain the hardware logical partitions (LPAR). Logical partitions CPU resources can be managed through IBM Enterprise Workload Manager which reflected the computing platform and upper application cooperation relationship (Nelson M et al. 2005).

4 THE COAL MINE SAFETY INFORMATION MANAGEMENT SYSTEM BASED ON CLOUD COMPUTING

4.1 *The overall system design*

Coal mine safety information management system based on cloud computing, aims to integrate the existing coal enterprises of traditional web information management system, with relying on the powerful data management capabilities to ensure safety production. Cloud Management System (CMS) is mainly composed of three modules, namely: the cloud monitoring data management system, the hidden danger cloud management system, and the evaluation of safety quality standardization cloud management system. void excessive notes and designations.

4.2 *The cloud monitoring data management system*

Under the actual production of coal mine will have a variety of sensors. The sensor data has the characteristics of mass, heterogeneity, and uncertainty. In digital monitoring system of coal mining enterprises which have been built in, to get the data from different sensors are often collected by different monitoring substation, often caused by hardware redundancy. Through the cloud computing platform can realize data mass storage and integration. Sensor data through data collector directly uploaded to the cloud which reduce redundant hardware and realize the software and hardware resources integration. For not construction of the digital monitoring system of coal mining enterprises, build the complete monitoring data management system needs only data sensor and data collector. Data through the cloud management reduce the hardware cost and improve the quality of the software services at the same time.

4.3 *The hidden danger cloud management system*

Digital management of hidden danger mode, in the already built information management platform of coal mine enterprises has been widely used. At present, the underground wireless network communication technology has been mature, relying on the portable digital terminal PDA or PAD as hardware platform, which can realize the real-time digital record of hidden danger and the personnel violate in the pit, totally abandon paper carrier. Compared to traditional computer information management system, based on the cloud platform of mobile intelligent terminal greatly shortens the processing time of the problem. For not building information management platform of coal mine enterprises, set up hidden danger cloud management system, only need a simple terminal hardware support, operating system virtualization of the cloud data resources needed can be automatically configured according to actual condition. Through the SaaS apps in the full life cycle management system application can improve operational efficiency, reduce operational costs.

4.4 *The hidden danger cloud management system*

Currently informatization of safety quality standardization evaluation work is at low level. Quality evaluation management is characterized by the traditional manual approach. Based on a cloud management platform and mobile terminal can be digitized in management of evaluation content. After input assessment data, the system will automatically generate related evaluation results and statistical information with print function. The system also can be added to the policy query and evaluation method study module at the same time, convenient query management personnel evaluation, improving the efficiency and accuracy of the work.

5 CONCLUSION

Mature development of cloud computing and wireless communications technology, provides a new train of thought to develop a new generation of integration of coal mine safety information management system. Safety management platform based on CMS integrated cluster, compared with the existing information management platform, has the following characteristics and advantages:

- Integrated cluster safety management system based on CMS is for the smooth transition of existing information systems. So based on the CMS can speed up the coal mine enterprise's safety informatization construction process, reduce the gap of informationization safety management between SMEs and large enterprise.
- Integrated cluster safety management system based on CMS is a efficient integration of existing information systems. Information management system based on CMS can realize the

maximization of data and information sharing, make the data format between departments to unity, get rid of the existing traditional management way of "information island".

- Integrated cluster safety management system based on CMS is the depth of the use of existing information systems. Cloud computing is the nature of service, based on the three management subsystem, to maximize make full use of existing resources, and to provide complete information chain for coal mining enterprises.

Treatment methods of coal mining subsidence area at South Lake in Tangshan city, Hebei province

Chunguang Xu & Ye Chen
China University of Mining and Technology (Beijing), Beijing, China

Zhong Li
Institute of Disaster Prevention, Langfang, Hebei, China

ABSTRACT: The mine environmental problems, such as mining collapse, karst collapse, ground cracks, land subsidence and water pollution, are produced by coal exploitation at the south lake of Tangshan city. Considering the species and distribution characteristics, stable subsidence and unstable subsidence, we'll conduct the geological disaster partition. Adopting scientific principles according to local conditions helps to achieve the purposes of management and protection.

1 INTRODUCTION

It's inevitable to bring about various destructive influences in the process of exploiting the mineral resources. Long-term large-scale and super-strength exploitation of mineral resources causes serious damage to the mine geological environment of our country. It's no time to delay taking the scientific management and treatment for mine geological environment, and there will be one practical significance to the system research of treatment technology of the mine geological environment (WU & CHEN 2010, WU et al. 2005, WU 2003, CHEN 2009). After more than 130 years' exploitation in Kailuan coal mine, the coal mine subsidence area has formed around the urban areas, especially in the south area. The coal mine subsidence area is full of weeds, rubbish everywhere and sewage with waste water, which seriously damages the city's environment and threatens the southern subsidence around the daily lives of residents. Therefore, aiming at the treatment of no less than 3 million square meters of subsidence area and building the center ecological park in the south lake are a beneficial project for people, which can protect the environment and reassure the people (WU 2005, WU et al. 2001).

2 THE BACKGROUND OF GEOLOGICAL ENVIRONMENT

South Lake is located in Tangshan city, Hebei plain, with a total area of 91.4 square kilometers. In general, it is higher in the northeast than southwest from the topography. The landform is alluvial-deluvial plain, which the structure is simple and the type is single, and the rock-soil engineering geological conditions are poor. It is in the meizoseismal region where the active faults distribute. The geological environment is markedly influenced by the exploitation of Tangshan mining branch company. The underground coal field in the south lake of Tangshan is located in the southwest of the northwest wing of Kaiping coal field, whose geological condition is much more complex. The stratums are Quaternary, Permian, Carboniferous and Ordovician from top to bottom. The total thickness of the coal stratum is about 500 meters, having more than ten coal seams. The hydrogeological condition is complex.

3 MAJOR MINE ENVIRONMENTAL PROBLEMS

3.1 *Mining collapse*

With the topography of low-lying of south lake area in Tangshan city, The mine drainage and the precipitation are collected here to form a lake sedimentation (Figure 1). The conditions around the subsidence lake are harsh, such as the slag field, coal gangue and pulverized coal accumulated disorderly. Land subsidence results in the constantly building askew and chapped, Ground fissure and widespread collapse pits. Deformation of the land is intensified by the expansion of the increasing scope mined. Meanwhile, the land appears large volumes of subsidence basin, ground fissure and funnelform collapse pit (WU & CHEN 2003). As

Figure 1. Subsidence lake.

the land is being cracked and rainwater is infiltrating, the original ecological balance has been broken greatly.

3.2 *Karst collapse*

There are a great many karst faults due to the faction of geological structure in this area. Karst morphology dominated by the large gap solution, followed by cave. Generally dissolved in fissures and gaps between layers based on fissures developed from its width 1~5 cm, larger up to 50 cm, and the distribution of it mainly strike NE and NW, partly developed and small. The overlying Quaternary soil structure suffers varying destructions under the influence of exploitation of ground water, "earth hole" collapse is more common. There have been several tubular collapse pits within the bounds of the southern coal mine in the south lake area.

3.3 *Ground fissure*

Directly associated with the Lake District ground fissure zone is generated by the Tangshan earthquake in Tangshan Shengli Road to Wangmatai fracture zone, belonging to the ground fissuers. It has the biggest scale and the highest regularity, with the total length about 11 kilometers. it overall strike NE30°, having multiple-unit fissures around, and the horizontal offset ranges from a few centimeters to hundreds of centimeters (ZHENG et al. 2002).

3.4 *Land subsidence*

With the increasing amount of groundwater, the table drops, forming a cone of depression. And the geotechnical mechanics of stratum is broken, which causes Hangu subsidence and Nanbao-Tanghai subsidence formed nearby Tangshan city (GUO et al. 2004). The south lake is located in the edge of Hangu subsidence and Nanbao-Tanghai subsidence. The cumulative quantity of the land subsidence is less than 300 mm and subsidence rate is less than 15.0 mm/a from 1983 to 2005.

3.5 *Water pollution*

The dirty water poured by residents nearby causes seriously water pollution in the south lake area of Tangshan. Polluted water of Qinglong river flows under Fenghuangtai, passing through Tangxu road into Qingtianjing. The amount of dissolved oxygen at the lake surface nearby Tangxu road is very small, only 0.42 mg/l to 0.62 mg/l, however, with a high value of COD. There are plenty of water blooms at some area of the lake surface. Xixingchi, which is also called the little south lake, dissolved oxygen highly, up to 10 mg/l, and pH is 8.43 to 8.63 (GENNARO & WILLIAM 1986).

4 PRACTICABLE TREATMENT TECHNOLOGY

4.1 *Treatment of subsidence*

4.1.1 *Relocation of residents*

Plenty of shanty towns nearby have been formed because of the constant expansion of subsidence regions. According to the comprehensive plan of the center ecological park construction made by the government, help the residents at coal mining subsidence area move out and take measures to retreat from geological disasters can reach the purpose of the environmental treatment. The immigrant villages at the subsidence area are total 17, that is 6097 families and 17042 persons (SANJEEV 2011, LATIMER 2012).

4.1.2 *Dig the lake and fill it*

28 square kilometers coal mining subsidence area in TangShan city has been planned and treated generally through digging the marsh area and filling the edge zone of subsidence areas. The bottoms of the large subsidence pits are fixed by the clay firstly for preventing from the percolation. After that, filled with cinders and covered soil finally. Generally, the thickness of the soil is 1 meter or more, which lays a foundation for the ecological recovery.

4.2 *Treatment of the land covered by solid waste*

The wastes made by coal mine exploitation form many waste-rock hills over a long time accumulation, including various rock compositions such as the coal gangue, sandstone, mudstone, shale, limestone and so on, and sometimes there are various wastes from the urban people. We adhere to the principle that we should effectively use the solid waste and comprehensively manage it. The

compact and hard waste-rocks are used to build the retaining walls, garden walls and garden plant pools. While the useless are piled with the treatment of slope stepped cutting. All of these lay a foundation for building mountainous of ecological park during the later period.

4.3 *Recover of the landscape*

The parking lot, leisure plaza and plants pool are built on the top of cutted slope of waste-rock so as to make a good use of the fields. The slope of waste-rock are protected by the air brick and the locking structure are made of the concrete, which benefit the growth of herbaceous plant and prevent the dust in the air. Planting large-scale trees in the surrounding of the artificial lake creates a garden landscape. The fences are planted on the both sides of the road instead of protective nets to prevent the tourist from going into the subsidence area and other unsafe fields (Figure 2).

4.4 *Treatment of water pollution*

The drain outlet is stemmed, the sewer network with more than 5300 meters long is embedding, and the waste water of subsidence pits is led into the treatment plant.

Building the waste water sewage sedimentation can achieve the fractional precipitation. Meanwhile, leading the waste water into the north of the pond where cattail, reed and other plants grow may attain the purpose of natural segregation, filtration and absorbing waste water.

We can knock through the disjunctive cesspits so that combine them into a whole big lake, and plant lotus with 5000 square meters, which can purify the lake water and form a special sights for appreciating the flowers.

We might build the lake sights with ornamental value and make use of the dam of the original pond to build a center island with its acreage of 2000 square meters. Building the wharf on the east of the lake makes the visitors can row on the lake (WOLFGANG & CHRISTIANE 1995).

Figure 2. Green belts for the safety protection.

5 EFFECT OF TREATMENT

The subsidence area where the mine geological disasters ever perplexed the people has became a beautiful ecological city park through a reasonable and effective ecological transformation. The original scene, such as the barren land, growing rankly weeds, waste water, coal ash, rubbish and gangue accumulated like a hill, has changed completely. Now it has became an ecological tourist area with a overlapped function including holiday villages, leisure areas, children park and extreme sports ground, so that it satisfies the demands of people's increasing spiritual culture and greatly promotes the development of the tourism in Tangshan city.

6 CONCLUSIONS

1. A series of environmental problems, such as mining collapse, karst collapse, ground fissure, land subsidence and water pollution, are produced by coal exploitation in the subsidence area of the south lake, Tangshan city, which seriously affect the people's daily life and production.
2. Considering the different mine environmental problems of the south lake, the different treatment technology are taken due to the influences for achieving the object of control and protection.
3. The construction of an ecological city at the south lake of Tangshan city can make good use of the characteristics of topography and turn the waste into the treasure. And then achieve the purpose of mine environmental treatment and development plan of building a livable city. The effect of the treatment is noticeable.

TBM tunneling in squeezing ground: Problems and solutions

H.S. Ma & J. Wang
CNNC Beijing Research Institute of Uranium Geology, Beijing, China

L.J. Yin
Ecole Polytechnique Federalede Lausanne (EPFL), Lausanne, Switzerland

ABSTRACT: The squeezing ground encountered in Tunnel Boring Machine (TBM) tunneling presents great challenges and may trigger the potential hazards without warning. A detailed understanding of such unfavorable condition is therefore critical to a successful bored tunnel. In this paper, a brief review on the definition and the factors related to squeezing condition is presented. The main problems involved and the corresponding mitigation measurements for the TBM tunnelling under squeezing ground are discussed as well. Finally, further researches to be conducted for better coping with these problems are emphasized.

1 INTRODUCTION

The squeezing ground behaviour experienced during TBM tunnel excavation, has caused great difficulties with major delays in construction schedules and cost overruns (Barla 2001, Ramoni & Anagnostou 2010). There are numerous cases involving squeezing phenomena, including: the Cristina tunnel in Italy, the Gotthard tunnel in Switzerland, the Simplon tunnel crossing the Italian-Swiss border, the Hartebeestfontein Gold Mine project in South Africa, the Uluabat Tunnel in Turkey, the Ghomroud water conveyance tunnel in Iran and so on (Barla 2001, Ramoni & Anagnostou 2010, Malan 2002, Ramoni & Anagnostou 2012, Farrokh & Rostami 2008, Schubert et al. 2006). These cases provide some insight into the ground response during excavation, as well as presenting the main potential difficulties and hazards for TBM tunneling in squeezing condition, with a typical example shown in Figure 1 (Schubert et al. 2006). This paper aims to provide a better understanding of such unfavorable condition by brief introduction of squeezing ground definition and influencing factors, and detailed description of the main problems related to TBM tunneling under squeezing condition. Moreover, the corresponding mitigation measurements are proposed from three categories: i) selection of TBM type and modification of TBM, ii) condition of ground and iii) optimization of TBM operation.

Figure 1. Failure of stiff lining at the Gotthard basis tunnel due to ground squeezing, after Schubert et al. 2006.

2 GENERAL DEFINITIONS OF SQUEEZING GROUND

As proposed by the International Society of Rock Mechanics (ISRM) (Barla 1995), squeezing rock is the time dependent large deformation, which occurs around the tunnel and is essentially associated with creep, caused by exceeding shear stress. Deformation may terminate during construction or continue over a long time period. (Furthermore, many other researchers also gave some different definitions but with common arguments of squeezing, please see the Ref of Barla (2001)).

The term "time dependency" involved in squeezing ground behaviour, is mainly due to the creep caused by exceeding a limiting shear stress creep and consolidation processes taking place around the tunnel (Deere. 1981, Aydan et al. 1993, Anagnostou & Kovari 2005).

3 FACTORS RELATED TO TBM PERFORMANCE IN SQUEEZING CONDITION

As TBM performance is the result of the interaction between rock and TBM machine, both of the rock mass properties and TBM design/operation parameters should be included for this issue. The factors influencing TBM performance in squeezing ground can be briefly summarized as shown in Table 1.

4 PROBLEMS IN SQUEEZING CONDITION FOR TBM TUNNELING

4.1 *Jamming of cutterhead, shield, back-up equipment*

Due to the particular excavation technology of TBM tunneling, the convergences which exceed 5% of the tunnel radius are to be considered problematical (Kovari 1996). When the friction produced by the squeezing ground acting on the cutterhead or shield cannot be counteracted by the available thrust, the TBM becomes jammed (Steiner 1996, Einstein 1989). It is the main challenge for TBM tunneling in squeezing ground due to high pressure by ground and core extrusion. Several factors as follows contribute to this problem.

1. Ground condition
   The squeezing behavior is associated with ground conditions, such as geological conditions, rock properties, the ratio of in-situ stress relative to rock mass strength, the groundwater condition, and so on. As stated by Farrokh et al. (2009), the rock mass in the shield jamming locations usually consists of schist, quartz veins and some soft interbedded graphite schist. In these locations, it is important for occurrence of ground squeezing if the strike of the schistosity is parallel to the tunnel axis.

   The double shield TBM was once jammed in a section of the Connection Works No. 7 tunnel of the Yellow River Diversion Project (YRDP) (D = 4.8 m, L = 13.52 km) in China (Shang et al. 2004). The existence of an interlayer shear zone in the lower part of the anticlinal core, together with local concentration of ground stresses caused a high rate of convergence (20–40 mm/h) of marls in the tunnel wall, which directly brought about TBM jamming and 9 days delay to release the machine.
2. Time-related factors (or advance rate)
   The danger of TBM blockage in a squeezing zone decreases with increasing advance rate. However, nobody can guarantee that high advance rates can be maintained throughout a squeezing zone. Several factors contribute to advance rate under such typical condition.
   i) Standstills: In cases where a TBM is forced to stop for a long period in squeezing ground, the still ongoing displacements then may squeeze the machine, making a restart difficulty (Barla 2001, Barla & Pelizza 2000). Based on the data by Ramoni and Anagnostou (2010), Table 2 gives the summary of standstill causes and the related jamming cases.
   ii) Excavation method and support technique: as stated by Barla and Pelizza (2000), the

Table 1. Factors related to TBM performance in squeezing condition

Ground condition parameters	TBM machine parameters	Operation parameters
Strength and deformability of rock mass; lithologic character; overburden; permeability; groundwater condition; orientation and thickness of discontinuities.	TBM type; length of shield; available thrust and torque; cutterhead design; back-up equipment design.	Advance rate; thrust, torque; standstill; overcutting; support method.

Table 2. Standstill causes and related jamming cases.

Standstill causes	Case	TBM type	Diameter/m	Resulting in…
Maintenance stop	Tunnel 38 of the Yindaruqin Irrigation Project, China	Double shielded TBM	5.54	TBM trapped
High extrusion rate of core	Gil-gel Gibe II Tunnel, Ethiopia	Double shielded TBM	6.98	Shield and segmental lining damaged
Holiday stops	Yacambú–Quibor Tunnel, Venezuela	Gripper TBM	4.80	TBM jamming
	Nuovo Canale Val Viola, Italy	Double shielded TBM	3.60	TBM jamming
Interruption of electric power supply	Evinos–Mornos Tunnel, Greece	Gripper TBM	4.20	Cutterhead jamming

major difficulty for open TBM's advancing in strongly converging and unstable ground derives from the difficulty of placing supports like steel sets, wire mesh and shotcrete, and the inability of these supports to counteract immediately the tendency of the ground to deform and squeeze.

In addition, if the proper backfilling of segmental lining was not achieved, it presents the impossibility of fully utilizing the installed thrust force, leading to TBM trapped, such as that experienced in the Stillwater Tunnel project (Ramoni and Anagnostou 2010) (USA, Double shielded TBM) and Los Rosales Tunnel (Colombia, Double shielded TBM).

iii) Shield length: compared with gripper TBMs, the Shielded TBMs with long shield are highly sensitive to rapid convergences and associated with heavy risk of blockage by converging rocks, if special technical precautions are not taken (Barla & Pelizza 2000).
iv) TBM thrust: high thrust is the prerequisite to maintain advance rate to rapidly pass the squeezing zone.

4.2 *Damage to support*

High pressures on the tunnel lining in the long term can lead to structural or functional failure of these supports. During the construction of water transmission tunnel in Yacambu, Venezuela (Wittke et al. 2005), the two open type TBMs faced extremely unstable ground conditions associated with high and rapid squeezing of the tunnel walls (see Fig. 2).

Figure 2. Water transmission tunnel in squeezing rock, Yacambu (Wittke et al. 2005).

In some occasion it was also necessary to cut down the already erected but deformed steel set due to heave squeezing, re-excavate the tunnel perimeter by hand-mining, and re-install the supports.

At the Faido multifunction station of Gotthard base tunnel project (Ehrbar 2008), the cutterhead had been changed from 8.80 m to 9.40 m in order to obtain more space for deformations and rock support. The deformation behind the cutter head became locally big, and there was a risk that the back-up installation could not pass through the excavated hole. Due to very large radial deformations and an influence of the second tube on the first (eastern) tube, some heavy damage unexpectedly presented in the rock support and lifting of the concrete floor (see Fig. 3).

4.3 *Specifically for different types of TBM*

1. Gripper TBMs: i) difficult to apply thrust due to reduced gripper action for gripper TBM; ii) more time for support installation such as steel sets, wire mesh and shotcrete; iii) the inability of these supports to counteract immediately the tendency of the ground to deform and squeeze; and iv) the reduced performance of the back-up system by squeezing ground behavior (e.g. re-profiling works, twisting of the tracks).
2. Shield TBMs: A higher frictional resistance has to be overcome due to larger area exposed to the squeezing pressure, and consequently, the risk of shield jamming is higher than gripper TBM if all other parameters being equal.

4.4 *Other main problems*

1. Inadmissible convergences of the bored profile, required to re-profile the tunnel if squeezing exceeding the limits.

Figure 3. Deformed steel rib in the floor at the end of yield phase (Ehrbar 2008).

2. Face instability (Barla 2001, Schubert 2000). The instability of the tunnel face is generally not a problem since any squeezing is excavated as part of the cutting process. However in severe squeezing conditions, the face extrusion may become important and it is difficult to control.
3. Difficult to control TBM direction in soft and heterogeneous grounds, e.g. when the machine is heading perpendicularly to the stratification or in case of bed separation and bulking (Barla 2001).

5 SOLUTIONS TO DEAL WITH SQUEEZING GROUND

5.1 *Selection of TBM type and modification of TBM*

1. Selection of TBM type. Based on the advantage and disadvantages of different TBMs listed in Table 3, select the TBM type depending on (Ramoni & Anagnostou 2010): i) how high the bearing capacity of the ground is in the gripper area; ii) how rapidly the convergences or ground pressure develop; iii) how much support had to be installed in the TBM area in order to stabilize the opening and control the deformation.
2. Modification of TBM. In special geological situations, due to the type of rock formation together with the tectonic actions and/or the overburden, immediate squeezing behavior the tunnel can occur and the TBM shall be designed to cope with these grounds. Some suggestions related to effective modification of TBM components are given in Table 4.

Table 3. Advantages and disadvantages of different TBMs (Ramoni & Anagnostou 2010).

TBM type	Advantage	Disadvantage
Gripper TBM	Shorter length greater flexibility of tunnel support	Lower thrust (gripper bracing problem) Lower AR (big support requirement)
Shielded TBM	Highly industrialized tunnel construction some recent technology higher thrust, torque	Longer shield length

5.2 *Condition of ground*

1. Apply proper support
   Two successful cases should be mentioned for this issue.
   i) The water transmission tunnel of the Yacambu project in Venezuela (Wittke et al. 2005). The tunnel is located in so-called squeezing rock (see Fig. 2). This tunnel was excavated by a tunnel boring machine (TBM-G) and supported by steel arches, shotcrete and anchors. However, the stiff support was overloaded because the rock adjacent to the tunnel became plastic due to high overburden. An adequate design would therefore have consisted of a shotcrete membrane with horizontal slots, fixed by yielding rock anchors (see Figs. 5–6). Such a support

Table 4. Modification of TBM components.

TBM component	Modification
Cutterhead	Larger cutterhead to have more space for deformation and rock support (Ehrbar 2008)
Power system	High thrust enough to overcome the resistance between the rock and shield
Cutterhead canopy	Shrinkable (see Fig. 4)
Overboring system	Increase the radial gap between shield/rock from 6–8 to 15–25 cm
Shield (Ramoni & Anagnostou 2010)	As short as possible Slightly conical As smooth as possible Bearing capacity, high enough for the ground pressure Higher deformability of the shield Flexible design of the rear part of the shield reduced rear shield diameter or collapsible rear shield design (Wittke 2005)
Back-up system (Ramoni & Anagnostou 2010)	To make the back-up trailers small enough relatively to boring diameter to gain some space in case of unexpectedly high ground deformations in the back-up area. Considering the intervention limitation in the back-up area when planning a TBM drive for squeezing ground and where necessary requirements must be formulated in the TBM specifications.
Mucking system design	Capacity should be attuned to the TBM advance rate, otherwise, it can cause packing of the muck around shield and then reduce the space available for deformations and may therefore lead to an earlier development of ground pressure upon the shield.
Support	Practically rigid support and yielding supports, for much information see Ref. (Ramoni & Anagnostou 2010)

would have allowed for radial displacements to enable the above cited arching action within the rock mass. After certain displacements combined with the partial closing of the slots, the remaining gaps would have had to be fixed thus creating a stiff support. This process is strongly time-dependent because of the time-dependent plastic behavior of the rock mass.

ii) Yacambú-Quibor tunnel (Schubert et al 2000). The 5 m diameter 23.3 km long Yacambú-Quibor tunnel is designed to carry water through the Andes from the Yacambú dam in the wet tropical Orinoco basin to the semi-arid but fertile Quibor basin, in western Venezuela. Over the 32 years (1976–2008) of construction approximately 30 different support designs were used and, in better rock conditions under moderate stress conditions, many of these designs were successful. However, in the very weak graphitic phyllites at depths of up to 1200 m below surface, squeezing could only be handled effectively by installing yielding support in a circular tunnel profile as shown in Figures 7–8.

2. Pre-treatment of the ground
Pre-treatment of the ground can be performed by grouting, reinforcement or drainage which are carried out basically either before or during the TBM drive (Ramoni & Anagnostou 2010):

Figure 4. Gripper TBM with shrinkable canopy used at Gotthard base tunnel (Herrenknecht 2009).

Figure 5. Shaft Konrad, yielding support in squeezing rock (Wittke et al. 2005).

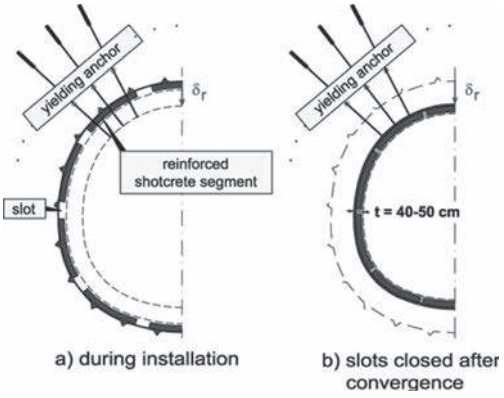

Figure 6. Yielding support, principle (Wittke et al. 2005).

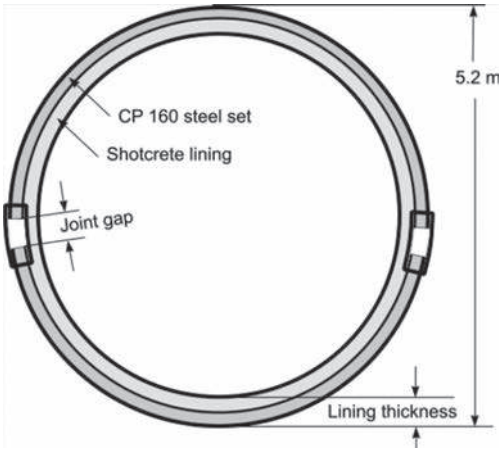

Figure 7. Design details of the yielding support used in the Yacambú-Quibor tunnel (Schubert et al 2000).

Figure 8. Assembled steel set with two sliding joints in the site workshop (Schubert et al 2000).

(i) The solution conducted before TBM drive is of course preferable as improvement work will not interfere with the TBM operation, however, it necessitates in nearly all cases the construction of an intermediate access tunnel or a pilot tunnel, which may also be technically demanding, costly and time-consuming. The pretreatment of the ground from the TBM itself during TBM drive does not require auxiliary structures, but slows down the TBM drive considerably. (ii) The applicability of grouting or drainage depends strongly on the ground characteristics. Squeezing rocks are unfavourable in this respect as they often have a high fraction of fines and, therefore a low permeability.

5.3 *Optimization of TBM operation*

1. Maintaining a high overall advance rate. by operational measures (applied systematically), appropriate construction site organization (necessary logistical precautions), cutting down standstill time as short as possible, also keeping necessary maintenance work, and considering holiday period and even the possibility and frequency of strikes (Ramoni & Anagnostou 2010).
2. Overboring. One of the effective measures to manage squeezing is overboring by overcutters, as shown in Figure 9, which can increase the radial gap between shield/rock from 6–8 to 15–25 cm, but the overboring technology still requires further development.
3. Deal with TBM jamming. Several solutions can be useful to free TBM as follows: providing high thrust, injecting proper lubricants to reduce the friction between outer shield surface and ground, and performing hand-mining (see Fig. 10) from the front shield and near the cutterhead (Barla 2001, Farrokh & Rostami 2009). If these measures still fail to work for a double shielded TBM, it has to perform openings on the telescopic shield at 4–5 m from the face and implement over-cutting through these openings.
4. Finding evidence of squeezing conditions during the excavation. This measure is very important and allowing the operator to prepare for upcoming unfavorable conditions. If known in advance, operators can implement measures to avoid TBM jamming and time-consuming activities of releasing the machine with manual labor. Two actions proposed by Farrokh and Rostami (2009) can be taken to perform squeezing prediction as follows:
   i) Based on TBM operational parameters (TBM thrust, torque) and some composite performance indexes. These parameters can play a very important role in predicting potential problems in ground conditions near the sections with high potential of squeezing. Preliminary findings show that unusual increase in re-gripping pressure, higher thrust than normal level, and sudden decrease in penetration rate are indicative of the upcoming squeezing situations.
   ii) Tunnel wall convergence monitoring method: directly measured by using a scaled instrument in the grout holes inside the segmental lining, or measured by comparing the available annular space around the segmental lining at the end of the tail shield (in vertical direction) and the annular space around the segmental lining in the non-squeezing ground.

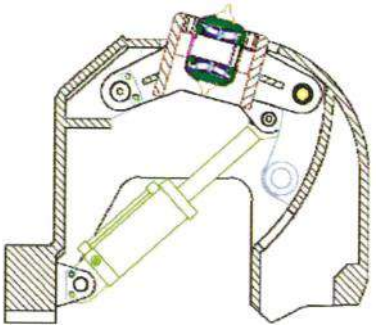

Figure 9. Robbins overcutters (Home 2009).

Figure 10. Hand mining around the front shield and stabilizing by wood timbers (Farrokh & Rostami 2009).

6 CONCLUSION

To better coping with squeezing ground encountered during TBM tunneling, several developments may be required as follows: the improvements of TBM technology for future applications; the fur-

ther study on fundamental theory and mechanism to better understand the rock-machine interaction under squeezing condition; the substantial attention given to prior engineering geological and hydrogeological investigations and analyses, in order to assist the flexible design of TBM tunneling.

ABSTRACT: Based on the theories of operations research, a mathematical model for the best escape route during mine fire time is built in this paper, which serves the multi-objective optimization process. An approximate search algorithm with multiple optimization objectives is proposed for the model based on heuristic algorithm, which could find out the shortest escape route from the multiple—weight escape route network by constructing auxiliary functions. Along with the study case of the mine fire emergency rescue system of a coal mine, the algorithm procedures are introduced, the convergence rate of the algorithm are analyzed, and the time complexity and the strengths of the algorithm are discussed. By this algorithm, decision makers can find out the optimum rescue route on the tunnel distribution sketch map of a coal mine, thus realizing the multiple optimizing targets, and providing strong technical support for mine fire rescue under mine.

1 INTRODUCTION

In the event of coal mine fire, there will be a serious threat to the lives and safety of the underground staff, so the mine fire is one of the major threats of the coal mine production safety. The Coal mine underground space is at a premium and the mine tunnel complex Unicom, it will generate a lot of heat, toxic and hazardous fumes in case of fire, and these toxic gases in the mine are more difficult to dissipate. Therefore, the pros and cons of the escape route will affect the degree of injury on the health of persons in accidents. Choose the best relief route and escape routes, however, are a more difficult task. Accidents and heavy casualties are due to the wrong choice of relief and escape routes during mine fire time at home and abroad. In order to assist the relief commander decisions, reduce errors, it is necessary to use the computer to choose the best relief and escape routes (GAO R et al. 2008, WAN D et al. 1994, WANG D M et al.).

The mine fire escape routes discussed in this article sometimes need to consider a number of optimization targets. With the development of computer technology, there have been some studies on the optimization of emergency rescue plan, and the shortest path algorithm is a classical algorithm to solve the optimization problem, such as Dijkstra algorithm, Floyd algorithm (YU G & Yang J 1998, Current J & Marsh M 1993). However, these algorithms are more often than not limited to single-objective optimization (GAO R et al. 2008, YANG H C & SUN B 2011, XIAO G Q et al. 2001). For the optimization of major emergency rescue programs discussed in this paper, multiple optimization goals need to be taken into consideration at the same time, so we need to find a workable compromise between these goals in the solution process. Current has summarized and classified the researches on multiple—objective shortest paths and he pointed out that the usual approach is by linear weighting of different targets or converting one goal into a constraint. However, on one hand, the weight of the first method is very difficult to determine, on the other hand, the constrained shortest path problem has proved to be an NP-complete problem, so sometimes it is not

possible to obtain the solution if we adopt the second method, which is obviously not suitable for the need of fast solution for the emergency evacuation optimization problem (GAO R et al. 2008, CURRENT J et al. 1990, WEI H et al. 2005, HAO G et al. 2007, LIU J et al. 2007).

A multi-objective optimization model of escape route and its algorithm are proposed in this paper, which can meet the need of optimizing the different goals of emergency evacuation at the same time and solving the results quickly. In this algorithm, the Dijkstra algorithm is called by constructing auxiliary function, and some of the optimization goals are converted into a constraint, then the structure weight shortest is iteratively solved to find the minimum value of the main optimization goal.

2 OPTIMIZATION MODEL FOR ESCAPE ROUTE DURING MINE FIRE ACCIDENTS

2.1 *Problem description*

The intricate paths in the vicinity of the roadway underground can be seen as a connecting network from the perspective of graph theory. In the network graph, the paths are equivalent to the edges and the paths' intersections are equivalent to the vertices. When the selection factors of escape route in the undirected network graph are given, the escape route optimization problem in the layout network of the entire roadway underground can be converted into a graph topology optimization problem.

In order to evacuate the affected people to safe areas in time during mine fire emergencies, it is very important to select the best program among the many possible alignments to assist evacuation. There are double impact factors in choosing the escape route for disaster victims: the disaster victims' prevailing time (generally measured by the "equivalent length" (XIAO G Q et al. 2001)), and the impact on the health of persons walking on the roadway (death, injury and so on).

Considering the roadway itself and the catastrophic impact, the influencing factors on human walking speed can be seen as a corresponding coefficient to calculate the equivalent length of the lanes when solving the best relief route (Li G 2000, Fu E J & Tang A D 2006, Li S L et a1. 1999),

$$L_{ij} = k_{\mathrm{h}} k_{\mathrm{t}} k_{\mathrm{g}} k_{\mathrm{v}} \cdot l_{ij} + \sum_{\mathrm{j}=1}^{n_{\mathrm{ob}}} l_{ijm} \tag{1}$$

where, L_{ij}, l_{ij} = equivalent length and actual length of the roadway between node i and j; l_{ijm} = equivalent length of the m-th access obstacles, $1 \le m \le n_{\mathrm{ob}}$; n_{ob} = number of local obstacles of the roadway between node i and j; k_{h}, k_{t}, k_{g}, k_{v} = influence coefficients which depend on the height of the tunnel, the tunnel transport, roadway slope and wind speed on the roadway respectively. The conditional probability p_{ij} of the various consequences (death, injury, etc.) of the personal Walking in the roadway between nodes i, j after mine fire occurs, can be calculated by the corresponding "probability variable" (STRICKLAND J A & FOUREMAN G L 2002, GUTH D J et al. 1997, LEEK K W 2002):

$$p_{ij} = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{Y-5} \exp\left(-\frac{u^2}{2}\right) du \tag{2}$$

where, Y = random variable, and $Y = k_1 + k_2 \ln(D_{ij})$; k_1, k_2 = risk parameters dependent on the type of the accident; D_{ij} = subjected dose of the thermal radiation or toxic gases when the accident victims walking in the roadway, it can be obtained through the human body the fragile model (ZHOU Y F & LIU M 2011).

As a classic problem of graph theory, the definition of the shortest path is to identify a path with minimum weight between two vertices in a weighted graph. If the equivalent length of the path is taken as the weight of the edge, the optimization goal of choosing the rescue route is to realize the minimization of the total equivalent length of the route between the rescue base and the affected location. And if the impact on the health of persons walking on the roadway is taken as the weight of the edge, the optimization goal is that the average death probability on the route does not exceed the total amount of available oxygen. For the policymakers of escape route optimization program, it is necessary to ensure the efficiency of the rescue work as well as the safety of the affected personnel underground, i.e., to find the shortest path in the network containing two weights.

In summary, in addition to the main goal, there is a secondary optimization objective considered in this paper, i.e. the limiting condition. Based on graph theories and methods, the rescue route optimization problem considered in this paper can be described as: for network G = (V, E) in which $V(G) = \{v_i\}$ is a set of nodes in graph G, any vertex $v_i \in V(G)$ corresponds to point (x_i, y_i) in the plane; $E(G) = \{e \mid e = (v_p, v_q) = (v_p, v_q); v_p, v_q \in V\}$ is the set of edges of graph G, $|E| = n_e$, $|v| = n_v$, $F_1(p)$ represents the total equivalent length of a route from the rescue base to the affected location, i.e., the main optimization objective function, $F_2(p)$ represents the the victimized degree of persons' health, on the route from the affected location to the safe area,

i.e., the secondary optimization objective function, and $F_1(p), F_2(p) \geq 0$. w_1 and w_2 are the corresponding weights of the edges to the primary optimization target and the secondary optimization target. Assign different weights to the edges of the graph G according to the two optimization objectives, and we can get the optimal rescue route from node s to node t. In this way, the isomorphic relationship is established between the optimization of rescue route during gas leak emergencies and a complete graph containing double weights. The shortest route problem is a classic problem in graph theory, but the traditional algorithms can't directly find out the shortest path of double-weighting network graph. So we need to establish a reasonable mathematical model and design a suitable algorithm for the model according to the specific situations in practice.

2.2 *Establishment of optimization model of rescue routes for mine fire emergencies*

In order to get the bi-objective path selection model of the time-varying network, suppose F_1 as the main optimization objective, and F_2 as the secondary optimization objective. P denotes a feasible path (applicable scheme) from node *s* to node *t,* and the bi-objective shortest path model can be expressed as follows:

$$F_1(p^*) = \min F_1(p) \tag{3}$$

$$F_2(p^*) \leq l_t \tag{4}$$

$$F_1(p) = \sum_{(i,j)\in p} w_{1_{ij}} \tag{5}$$

$$F_2(p) = \sum_{(i,j)\in p} w_{2_{ij}} \tag{6}$$

Where, p^* = optimal solution for the model if p^* can satisfy both formula (3) and (4); P = collection of all feasible paths from node *s* to node *t,* $p \in P$; S = collection of the paths that meet equation (4); w_{1ij} = the target weight of the edge (v_i, v_j); w_{2ij} = restriction weight; l_t = maximum permissible value of the secondary optimization objective.

3 ON ALGORITHM FOR THE BEST ESCAPE ROUTES DURING MINE FIRE EMERGENCIES

In 1996, Zhan and Noon tested with actual traffic network 15 of the 17 algorithms previously tested by Cherkassty, and the test results showed that the fastest algorithm to calculate the shortest path is the Dijkstra algorithm. The Dijkstra algorithm is only applicable to solving the shortest path for the network with one weight, and cannot directly solve the shortest path problem of network graph with double weights (CURRNT J et al. 1990). An optimization model of rescue route and its algorithm are proposed in this paper, which can meet the need of optimizing the multiple goals at the same time and solving the problems quickly.

3.1 *Auxiliary functions and their properties*

In order to solve the shortest path problem for the double weighting network, a new weight for graph G is constructed with the target weight w_1 and limit weight w_2 and w_3, which is expressed as $w = \alpha w_1 + (1 - \alpha) w_2$, and $w_2 = (k_1 w_2 + k_2 w_3)$ $(0 \leq \alpha \leq 1)$. If there is a feasible path *p* from the specified source node *s* to the destination node *t,* a function can be established as follows:

$$f(\alpha) = \sum_{e_i \in p} \left[\alpha w_1(e_i) + (1-\alpha) w'_2(e_i) \right] \tag{7}$$

For any $\alpha \in [0, 1]$, p_{st} is the shortest path that satisfies min $f(\alpha)$ by Dijkstra algorithm. According to formula (5), (6), the corresponding target function values $F_1(p_{st})$ and $F_2(p_{st})$ of p_{st} can be obtained respectively. There is also a corresponding value *a* in the interval [0, 1] for each value of $F_1(p_{st})$ (also $F_2(p_{st})$). $F_1(p_{st})$ and $F_2(p_{st})$ are actually functions of the parameter α, respectively referred to as $F_1(p) = f_1(\alpha)$ and $F_2(p) = f_2(\alpha)$, wherein $0 \leq \alpha \leq 1$ and $p \in$ P. These two functions have the following properties:

Property 1: $f_1(\alpha)$ is a decreasing function on [0, 1] with its value minimized when $\alpha = 1$; $f_2(\alpha)$ is an increasing function on [0, 1], with its value minimized when $\alpha = 0$.

Proof Procedure of Property 1: Apply the Dijkstra algorithm and we obtain p_{st1}, p_{st2} that respectively satisfy min $f(\alpha_1)$ and min $f(\alpha_2)$ and $\alpha_1 < \alpha_2$. Based on equation (5) to (7), $\alpha_1 \cdot F_1(p_{st1}) \leq (1 - \alpha_1) \cdot F_2(p_{st1}) \leq \alpha_1 \cdot F_1(p_{st2})$ $(1 - \alpha_1) \cdot F_2(p_{st2})$, $\alpha_2 \cdot F_1(p_{st1}) \geq (1-\alpha_2) \cdot F_2(p_{st1}) \geq \alpha_2 \cdot F_1(p_{st2}) + (1 - \alpha_2) \cdot F_2(p_{st2})$. So $\alpha_1 (F_1(p_{st1}) - F_1(p_{st2})) + (1 - \alpha_1) (F_2(p_{st1}) - F_2(p_{st2})) \leq 0$, $\alpha_2 (F_1(p_{st1}) - F_1(p_{st2})) + (1 - \alpha_2) (F_2(p_{st1}) - F_2(p_{st2})) \geq 0$. Also $0 \leq \alpha_1 < \alpha_2 \leq 1$, so $F_1(p_{st1}) - F_1(p_{st2}) \geq 0$, $F_2(p_{st1}) - F_2(p_{st2}) \leq 0$, i.e., $f_1(\alpha_1) \geq f_1(\alpha_2)$, $f_2(\alpha_1) \leq f_2(\alpha_2)$. So it can be concluded that $f_1(\alpha)$ is a decreasing function, and $f_2(\alpha_1)$ is an increasing function. As $0 \leq \alpha \leq 1$, so $f_2(\alpha)$ has a minimum value when $\alpha = 0$, and $f_1(\alpha)$ has a minimum value when $\alpha = 1$.

Proof Procedure of Property 2: When $\alpha = 0$, $w_3 = w_2$, then min $f(0) =$ min $F_2(p) = f_2(0)$. If $f_2(0) > l_t$, then p^* has no solution. If the path p_{st} that satisfies min $f(\alpha)$ exists and $\alpha = 1$, $w_3 = w_1$, then min $f(1) =$ min $F_1(p) = F_1(p_{st})$ (wherein $p, p_{st} \in$ P). If $f_2(1) \leq l_t$, it can be concluded that $f_2(\alpha) \leq l_t$ is true of all

$\alpha \in [0, 1]$ according to the properties above. And according to formula (1), (2), $p^* = p_{st}$.

If the interval [0, 1] is divided into n subintervals of equal span, $k = 0, 1, 2,\ldots, n - 1$. Assume $\alpha = 0$, and we get the path p_0 that satisfies min $f(\alpha)$: $f_2(0) = l_{t0}$. Assume $\alpha = 0$, and we get the path p_1 that satisfies min $f(\alpha)$: $f_2(1) = l_{t1}$. Based on the above properties of the constructed auxiliary functions, we can deduce the following conclusions:

Conclusion 1: When $\alpha = k$ / n, the path p_{st} that satisfies min $f(\alpha)$ exists, and as $f_2(\alpha) = l_t$, there can be no other path $p \in$ P that satisfies both $p \in$ S and $F_1(p, s, t) < F_1(p_{st})$.

Conclusion 2: If the path p_1 that satisfies min $f(\alpha)$ exists when $\alpha = k/n$, and $f_2(\alpha) < l_t$, and the path p_2 that satisfies min $f(\alpha)$ exists when $\alpha = (k + 1)/n$, and $f_2(\alpha) > l_t$, then according to Property 1 and 2, it can be concluded that there may be another path $p \in$ P that satisfies $F_2(p_1) \le F_2(p) \le l_t$, and $F_1(p_2) \le F_1(p) \le F_1(p_1)$.

Conclusion 3: If we assign to a all the possible of k / n ($k = 0, 1, 2,..., n - 1$), and solve all paths that satisfy min $f(\alpha)$, we can obtain the trend curves of the two objective functions f_1 and f_2. According to f_1 and curve f_2, if the limit of the secondary optimization goal is set differently, then we will obtain different optimal solutions of p^*: if $l_t \ge l_{t1}$, then $p^* = p_1$; if $l_t = l_{t0}$, then $p^* = p_0$; if $l_t \ge l_{t1}$, then p^* has no solution and if $l_{t0} < l_t < l_{t1}$, then a series of sampled values of the optimal solutions that satisfy $f_2(\alpha) \le l_t$ will be obtained in the interval [0, 1] by applying the segmentation method, and the path that satisfies min $f_1(\alpha)$ among these sampled values is the optimal solution p^*.

3.2 *Optimization search algorithm*

Assume that the optimal path p^* from the source node s to the target node t exists, $\alpha \in [u, v]$ (wherein $0 \le u, v \le 1$), from Conclusion 1 and 2 we know that if path p_u and p_v that satisfy min $f(\alpha)$ exist when $\alpha = u$ and $\alpha = v$, and $f_2(u) < l_t$, $f_2(v) > l_t$, then p^* can be determined within interval $[u, v]$ by the previously constructed auxiliary functions. The interval $[u, v]$ is referred to as the approximate range of the optimal path. And path p_u is an approximate solution of the optimal path, referred to as p^{app}. If the path that satisfies min $f(\alpha)$ exists and is obtained when $\alpha = \alpha^*$ i.e., $f_2(\alpha^*) = l_t$, then the path obtained is the optimal solution p^* that we mean to find.

In accordance with the properties and conclusions in the Section 2.1, if the $[u, v]$ is divided into n subintervals of equal span,, $k_i = 1, 2,\ldots, n - 1$, and if there exists an optimal or approximate optimal path, then we can search iteratively for the solution in the current approximation interval $[u, v]$ until the optimal solution is obtained. The path that satisfies min $f(\alpha)$ can be obtained by calling the Dijkstra algorithm. Therefore, steps of the bi-objective optimiFation search-type algorithm can be described as follows:

1. $\alpha \leftarrow 1$, the Dijkstra algorithm is called to seek path p_1 that satisfies min $f(\alpha)$ from the source node s to the destination node t.
2. If $F_2(p_1) \le l_t$, $p^* \leftarrow p_1$, the algorithm ends; else $\alpha \leftarrow 0$, the Dijkstra algorithm is called to seek the path p_0 that satisfies min $f(\alpha)$ from the source node s to the destination node t; else if $F_2(p_0) > l_t$, there is no solution, then the algorithm ends; else if $F_2(p_0) = l_t$, $p^* \leftarrow p_0$, the algorithm ends; else $p^{app} \leftarrow p_0$, $u \leftarrow 0$, $v \leftarrow 1$, $i \leftarrow 1$.
3. $\Delta \leftarrow (v - u) / n$, $k \leftarrow 1$.
4. $\alpha \leftarrow u + k \cdot \Delta$, the Dijkstra algorithm is called to seek the path p_{ik} that satisfies min $f(\alpha)$ from the source node s to the destination node t.
5. If $F_2(p_{ik}) = l_t$, $p^* \leftarrow p_{ik}$, the algorithm ends; else if $F_2(p_{ik}) < l_t$, $p^{app} \leftarrow p_{ik}$, $u \leftarrow \alpha$, if $k = n - 1$, go to step (7); else $v \leftarrow \alpha$, go to step (7).
6. $k \leftarrow k + 1$, go to step (4).
7. $i \leftarrow i + 1$, if $i \le m$, go to step (3).

Take the disaster rescue project of a coal mine in Xuzhou as an example. Selected a site of the accident, and then import the geographic information data of roadway underground. The affected location, node (0, 0), is the source node, and the node (3, 2) is the destination node. The path network between the source node and the destination node is defined as a network diagram, the roadway being the edges of the graph, and the intersections being the nodes of the graph. The number of nodes demonstrates the scale of the graph. According to the optimization objectives, the equivalent

Table 1. Input data of original problem.

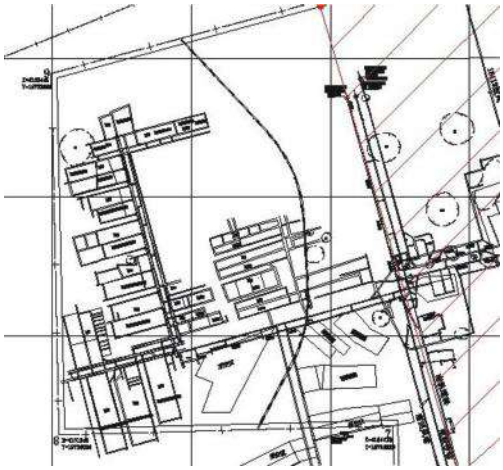

Figure 1. Mine roadway layout diagram.

length of the route and the death probability on the roadway on the path are three different weights of the edges. Assign random weights to each edge of the graph, and compile and run the optimization search algorithm, then we can obtain the best escape route from node (0, 0) to node (3, 2). For the input parameters and the optimization results, see Table 1 and Table 2, where the limit value of total oxygen consumption is 51 ml. Compared with the Dijkstra algorithm, the obtained optimization solution by applying the optimization search algorithm can meet the optimization objectives of the equivalent length and the death probability on the roadway at the same time. Mine roadway layout diagram seen in Figure 1.

The user layer of the bi-objective optimization system is developed in c # language of the. net architecture. The underlying layer is developed by using the NetworkX Library of Python and directly calling the packaged Dijkskra algorithm. The data can be imported from EXCEL or dynamically read from the database (ZHOU Y F & LIU M 2011, ZHOU Y D 2008).

4 PAPER SUBMISSION

In this paper, the mathematical model of the rescue route with multi-objective optimization during mine fire emergencies is built by applying the graph theory and optimization method in operations research, and the optimization search algorithm for the model is proposed. The weight of the path network in multi—objective optimization problems is easily determined by applying this algorithm, the convergence of the algorithm is faster, and the optimal solution obtained is an approximate optimal solution. The model is applicable not only to the rescue route optimization problems, but also to other optimization problems.

The proposed algorithm is not only helpful to the decision makers to solve the problems of emergency evacuation route optimization, but also to propose problems based on the two trend curves of objective functions by applying the algorithm.

ABSTRACT: Due to sewage affect on the environment becoming more and more seriously, sewage of mine was needed to treat urgently. In this paper, we have used the Sequencing Batch Reactor Activated Sludge Process to meet the needs of drainage control system, but the method was so complicated. Only automatic control part of this method was realized, strengths of Sequencing Batch Reactor Activated Sludge Process were played. Programmable Logic Controller from Mitsubishi FX2N Series was used in the automatic control system of sewage treatment with stable operation, low cost, good effect and so on.

Keywords: Sequencing Batch Reactor Activated Sludge Process; sewage treatment; Programmable Logic Controller

1 INTRODUCTION

The problem of mine sewage must be urgently resolved due to the increasing sewage problems from coal mine on the surrounding environment. According to different principles of wastewater treatment technologies, wastewater treatment technology was divided into physical method, chemical method and biological method. Among, biological method was defined that organic pollutants from sewage water were converted and absorbed by the degradation roles of microbial biological. In common, biological methods can be divided into activated sludge method, AB method, bio-film method, oxidation ditch method, and so on.

SBR method is the sequencing batch reactor activated sludge process, which is an activated sludge wastewater treatment technology by continuous feeding, intermittent drainage and cycle intermittent aeration. SBR is a predecessor of Fill-and-Draw system by intermittent operation, which is an improvement of activated sludge reactor fully produced by the early twentieth century (Wang Dayu 2001). In 1912, Clark and Gage form the United Kingdom had found that long time aeration of the wastewater will produce sludge, and water quality will be improved. In 1914, Alden and Lockett had found that the aeration of the sewage were static precipitated, the clean water were tossed away and the sludge were leaved in the bottom for the next wastewater treatment. The time used in the waste water treatment was significantly reduced by above method (Li Hai, 2002). However, due to some technology problems could not be solved technical such as cumbersome manual management, monitoring technology backward, aeration equipment blocked etc., we found it difficult to expand the applications at that time. In the early seventies, R. Irvine and other researchers from NaMe Dame University in the United States had proposed that SBR can be used as a better alternative technology in the continuous flow activated sludge process (CFS) by compared and researched the characteristics of SBR and CFS in the experiments (Wang Youle 2002). In the 80s of 20th century, due to the rapid development and application of automation and computer technology in the field of wastewater treatment, the activated sludge wastewater treatment technology had gain significant progress (Zhang Yu 2009). Since mid-90 s, the research and application of SBR technology were begun in our country, but most SBR technology was in the pilot stage or in the application stage of small sewage treatment.

2 SBR PROCESS FLOW

SBR is a biological method, which is an activated sludge wastewater treatment technology under intermittent aeration. Different from the traditional wastewater treatment process, the operation mode of space partitioning was placed by time division technology, steady-state biochemical reactions was placed by non-stable alternative technology; the traditional dynamic precipitation

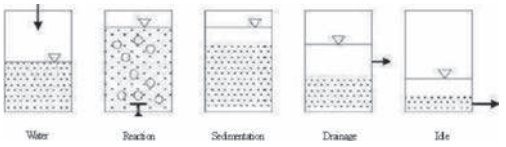

Figure 1. Five processes of SBR.

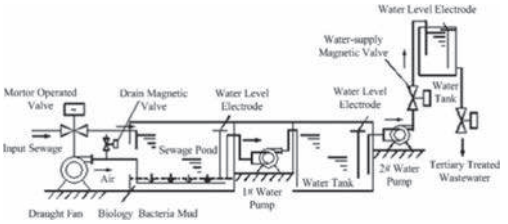

Figure 2. Wastewater treatment system schematic.

was placed by ideal standing precipitation technology in the SBR technology. SBR process technology is an advanced sewage treatment systems, which including the follow steps (Nandalal K D W 2003), that is, regulation, primary sedimentation, aeration, secondary sedimentation and biological nitrogen removal process in one pool. According different time to operate various steps, the whole process were run in a pool again and again, simple process, compact and reasonable.

The above technique can effectively remove BOD5 and Suspended Solids (SS) in the wastewater. Nitrogen compounds were converted to nitrate in the wastewater, and then be converted to ammonia, so the concentration of ammonia (NH_3-N) will be significantly reduced in the output water. SBR was mainly used in small-scale wastewater treatment process. In this paper, the automatic control system of sewage treatment from mine was designed. A partition wall was placed in the SBR reaction tank, which divided reaction tank into two parts, pre-reaction zone and the main reaction zone. There was a connected hole in the bottom of the wall. Water, reaction, sedimentation, drainage and idle five processes (Otterhl R, Grottker M 1997) in the each cycle are carried out in the same pool again and again, shown in Figure 1.

3 DESIGN OF ELECTRICAL CONTROL SYSTEM

SBR technology is a more advanced process technology due that SBR meets the basic needs of sewage treatment of coal mine. However, the typical shortcomings of SBR method is operated complexity, SBR method could play to its strengths after achieve automatic control. Although some sewage treatment plant have automated to some extent, most of the traditional control methods were used, namely, control ineffective. Time process control are mainly based on the pre-set time to implement automatic control from five running phase of SBR, that is, water, reaction, deposition, emissions, idle. However, sewage quality and quantity were varies with time, the sewage treatment process has significant time variation, so the dynamic behavior and operating characteristics must be more considerate. Sometimes, the concentration difference between organic matters were several times, if SBR method was used to control on the same response time, the quality of sewage treatment were constrained due to run water quality fluctuations (Zeeman G, Sanders W 2000). A more effective control method was required to ensure reliable operation of treatment systems in the method of SBR.

3.1 *Technical requirements of SBR wastewater treatment process*

SBR wastewater treatment technology is a highly efficient wastewater reuse technology, which used advantage bacteria technology to treat on life wastewater. The treated water can be used to irrigate green areas, flowers, flush toilets and vehicles, so as to conserve water resources. The program of SBR wastewater treatment system must fully consider narrow features in the life area to make the devices small, stable, less investment purposes. Wastewater treatment efficiency were directly affected by bacterial metabolism due to environmental temperature change in the wastewater treatment process, so a buried structure treatment pond was used to reduce the temperature effect of the wastewater treatment.

Meanwhile, considered SBR parameters change, hardware design and equipment debug complex in the process of wastewater treatment, using advanced PLC control technology can improve the efficiency of SBR wastewater treatment and easy to operate. SBR wastewater treatment system were composed by the sewage treatment pond, clear water tank, water tank, electric control box and pump, Roots blower, electric valves, solenoid valves and other components. Level switches were set to detect the water level of ponds and tanks in the sewage treatment pool, clear pool, water tank. The schematic of SBR wastewater treatment system was shown in figure 2.

3.2 *Power equipment of SBR wastewater treatment system*

Three-phase AC induction motors were used in the power equipment (pump, Roots blower,

electric valves) of SBR wastewater treatment system, waterproof and moisture-proof type of motors and solenoid valve were matched. 1# Clean Water Pump: Vertical Centrifugal LS50–10-A, head 10 M, flow 29 M3/h, 1 kW; 2# clean water pumps: vertical centrifugal pumps LS40-32.1, head 30 M, flow 16 M3/h, 3 kW; aeration Roots Blower: TSA-40, 0.7 M3/Min, 1.1 kW; electric valve: body D97A1X5-10ZB-125 MM, electrical equipment LQ20-1, 380V/60 W (three phase), torque 200 N·M, speed 1r/Min.

Consider of the interference performance, corrosion resistance electrodes were used in the level detection switch of water pool, clear pool, water tank. With PLC own 24 V DC power supply, the power supply capacity were considered when external load. The third grounding was used to improve anti-jamming capability in the PLC ground terminal.

4 HARDWARE DESIGN OF CONTROL SYSTEM

4.1 *Main circuit design*

Define abbreviations and acronyms the first time they are used in the text, even after they have been defined in the abstract. Abbreviations such as IEEE, SI, MKS, CGS, sc, dc, and rms do not have to be defined. Do not use abbreviations in the title or heads unless they are unavoidable.

1# water pump M1, 2# Pump M2, aeration fans M3 were respectively controlled by the main circuit contactor KM1, KM2 and KM3. Electric valve motor M4 was controlled by AC contactor KM4 and KM5 to complete open and close function of valves. The overload protection of Motor M1, M2, M3 and M4 were implemented by thermal relay FR1, FR2, FR3 and FR4. Thermal protection switches with closed were also equipped with electric valve motor M4 to achieve dual protection of valve motor M4. Short-circuit protections of the load circuit were achieved by the Fuse FU1, FU2, FU3 and FU4. The short circuit protection of AC control loop and PLC control loop were respectively realized by FU5 and FU6. The main control circuit figure of SBR wastewater treatment system was shown in figure 3.

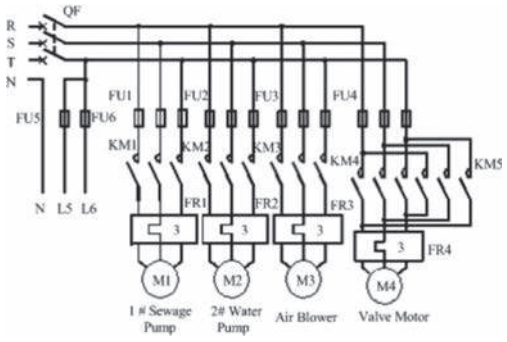

Figure 3. Main electric circuit of SBR wastewater treatment control system.

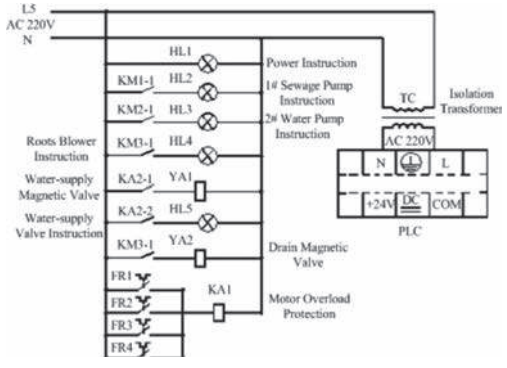

Figure 4. AC control circuit of SBR wastewater treatment system.

4.2 *AC control circuit design*

The isolation transformer TC was used in the PLC power supply circuit to prevent power interference. According to the electricity consumption of PLC, isolation transformer TC was configured with the standard, variable ratio of 1:1, the capacity of 100 VA transformer. The power instruct lights HL were set in the control circuit, that is, 1# clear water pump M1, 2# clear water pump M2, indicating lamps HL1, HL2 and HL3 were also set in the aeration air blower M3. The above instruct lights were controlled auxiliary switch of contact device KM1, KM2 and KM3. The overload protection of M1, M2, M3 and M4 were realized by four thermal relay FR1, FR2, FR3 and FR4. Overload protect was composed by closed-switch of contact KM1 and intermediate relay KA1, KA1 has also played the role of voltage conversion, the 220 V AC signal was converted into DC 24 V signals, which was sent into the PLC to complete overload control.

Water-supply solenoid valve YA1 and indicator lamp HL1, drain valve YA2 were controlled by the contactors of intermediate relay KA2 and KA3. The AC control circuit of SBR wastewater treatment system was shown in figure 4.

4.3 *PLC control circuit design*

The schematic diagram of PLC control circuit in the SBR wastewater treatment system was shown

of power source in the output circuit. In the input circuit, the signal power was supplied by 24 V DC power of PLC. With relay output, all COM ports were short circuit to access to positive terminal of DC 24 V power source. The input and output interface functions of PLC in the SBR wastewater treatment system were shown as table 1 and table 2.

5 SOFTWARE PROCESS OF CONTROL SYSTEM

According to operation sequence and restriction relations of each controlled objects, spatial distribution of PLC registers were determined, the functions of special-purpose register were confirmed, so control system were programmed. The flow of wastewater treatment systems was shown in figure 6.

PLC controller from Mitsubishi FX2N series were used in the treatment system of coal mine wastewater control by the blower, water pump, trip

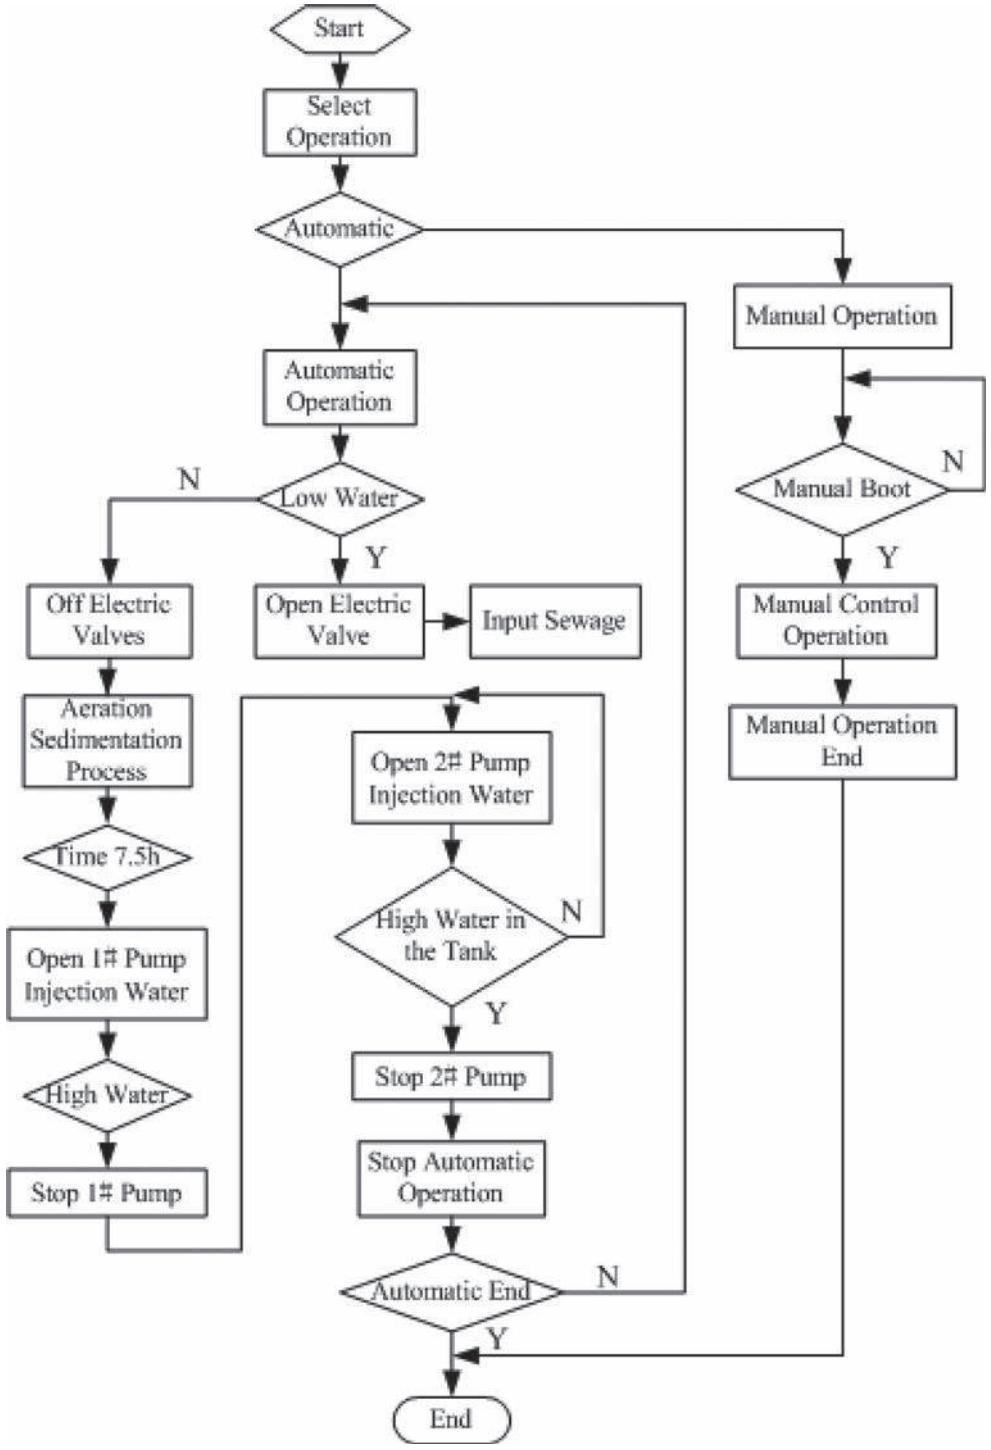

Figure 6. Control flow of SBR wastewater system.

switches, remote input/output switching value and the liquid level, flow and other analog variables to achieve automatic control of wastewater treatment areas. Sewage from mine was treated through the SBR to meet the national emission standards, which stable operation, low cost and good effect. Mine sewage was treated by the SBR method to irrigate plants, clean toilets, etc. Not only were solved of water shortage problem, but also to generate good economic and environmental benefits.

Phosphorus and Nitrogen have not considered removing in the existing activated sludge and biofilm process. Activated sludge oxidation ditch and SBR method were able to play the remove role of nitrogen and phosphorus, but it is ineffective in the small system of sewage treatment. Therefore, the removal functions of nitrogen and phosphorus should be considered to further study in the small wastewater treatment facilities. Meanwhile, with the improvement of environmental requirements and management constraints, assembly series, closed, automation and efficiency will be further development directions in small-scale sewage treatment facilities on mine.

A brief analysis of electromagnetic interference caused by the electrical and electronic equipments in the underground coal mine safety monitoring system

Xingzhi Hu, Jikun Wang, Xuezhe Li & Feiji Ding
North China Institute of Science and Technology, Yanjiao, Beijing-East, China

ABSTRACT: The safety monitoring system is one of the most essential components for the safety protection system in the production process of the coal mine. The number of power electronic equipment such as inverter and other monitoring systems for has risen steadily. This paper introduces the principle of electromagnetic interference and the working principle of the inverter. We summed up the impact of the inverter to the monitoring system, carried out our solution method to the inverter harmonic interference phenomena which may cause side effects to the hardware. In the application field, this paper has also made a certain reference and guidance to the mine safety production.

1 INTRODUCTION

Coal mine safety monitoring system can synchronously transmit the underground circumstances to the monitoring centre up to the ground to detect the coal mine production and production failure.

The introduction of this technology in the field of mine safety can be briefly described as follows:

1. Form a centralized real-time mine production monitoring system from the company to the counties, from the countries to the provincial cities within a certain range by the implementation of computer networking: real-time monitor coal mine production safety situation in the region, especially the underground methane concentration;
2. Take timely operations to disposal emergency cases: immediately make adjustments to the operation mode; instantaneously stop the underground production, rapidly withdrawal underground miners.

According to state regulations, most of the mines have been equipped with a safety monitoring system. For the sake of safe production, we need to create a system which can provides us an intuitive, reliable means to command and control coal disasters, offer us simple and scientific decisions to effectively get rid of the coal mine methane disaster, and curb the accident-prone tendency at the same time.

Currently, the coal mine safety monitoring system is a computer network-based digital surveillance system. Based on the computer networks and computer software, the technology of the coal mine safety monitoring system is a integrated technology which involves with information industry and industrial. It is the result of the development and improvement of modern control technology, digital communication technology and microelectronics.

The base-band transmission and out-of-band transmission are the main communication methods in domestic coal mine safety monitoring system. For the sake of the long-distance, transmission cable in general and underground power cables are arranged in parallel, large-scale mechanical and electrical equipment frequently run, start-up and shutdown will produce a strong electromagnetic interference, so the band transmission (such as FSK, PSK, PFSK MSK etc.) is used frequently in the monitoring system at the mine sites. Theoretical analysis shows that the band transmission using time division baseband transmission (e.g., RS-232C, RS-485, etc.) has obvious advantages. Among all kinds of band transmission methods, FSK the most suitable for coal mine applications because phase mutation will not emerge in this information transmission conversion, it can not only can effectively improve the communication distance of the system, but also have significant anti-jamming capability.

However, with the frequent start mine of information technology, the continuous progress of automation, the use of new high-power electronic devices, high-power electrical equipment and the use of radio frequency equipment, down whole electromagnetic environment is getting worse, causing serious electromagnetic radiated interference. Electromagnetic interference weakens the controlling signal and the detection signal. Severe

damage to the system may leads to a correct detection signal or disorders of the control system. Strong Electromagnetic Interference (EMI) can even cause damage to the system's hardware or microprocessor system program is running out of control, leading to control failure. Consequently, large numbers of false alarms in the safety monitoring system equipment may leads to accidental power failure which means a certainly lowing credibility of the information.

2 THE PRINCIPLE OF THE ELECTROMAGNETIC INTERFERENCE

Electromagnetic interference may result in the degradation in the performance of the device, the transmission channel and the system. On account of the different interference sources, electromagnetic interference can be divided into natural disturbance interference and human disturbance interference. Natural disturbances including cosmic interference, the day electrical interference and lightning impulse; human disturbance including industrial interference, radiation interference, conducted interference, crosstalk, the antenna end of conducted interference, wideband interference, narrowband interference harmful interference, high-power effect and electromagnetic pulse interference. All electromagnetic interference generated by the three basic elements of portfolio: sources of electromagnetic interference, the interference energy-sensitive receiver, the sources of electromagnetic interference transmitted to the receiver medium channel.

The sources of electromagnetic interference issue of electromagnetic energy transmitted through the intermediary channel to the interference energy sensitive receiver, the receiver shall exhibit some form of "response", and the "effect" of interference. (shown in Figure 1)

3 THE WORKING PRINCIPLE OF THE FREQUENCY CONVERTER

Excellent control performance, obvious energy-saving effect, easy to adjust and maintenance, smooth to start, the frequency converter technology is an all-star technique in the safety monitoring system. With variable speed technology matures and the inevitable trend of energy conservation requirements, devices based on inverter technology are increasingly being used in mine production.

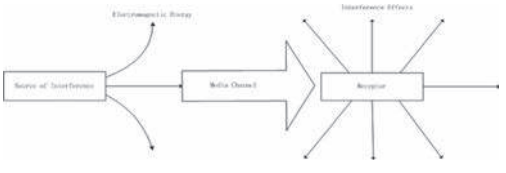

Figure 1. The working principle of electromagnetic interference.

4 HOW DOES THE INVERTER AFFECT THE MONITORING SYSTEM?

The inverter, as a power electronic devices, itself is a source of interference, so the impact of the monitoring system has brought great damage to the underground communications and safety monitoring system.

4.1 *Increase data collection errors*

The signal input channel interference immersed in the measuring unit of the microcomputer system and is superimposed on the useful signal, so that the data acquisition error increase, especially when a weak signal when the sensor output is relatively more intense interference.

4.2 *Failure of the monitoring state*

Usually the control of the microcomputer output signal, and less susceptible to outside interference, but the microcomputer outputs a control signal to the input signal and this signal is often based on the status of certain conditions the logic processing result, if this status of this input signal is subjected to interference introducing false status signal will result in increased output control error or malfunction.

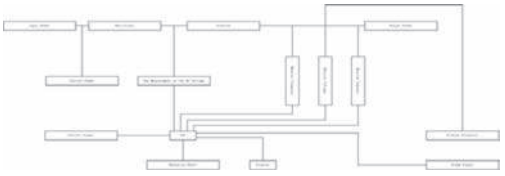

Figure 2. The working principle of the frequency converter.

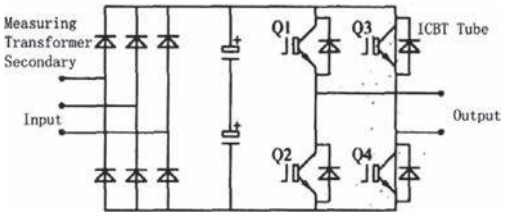

Figure 3. The inverter unit.

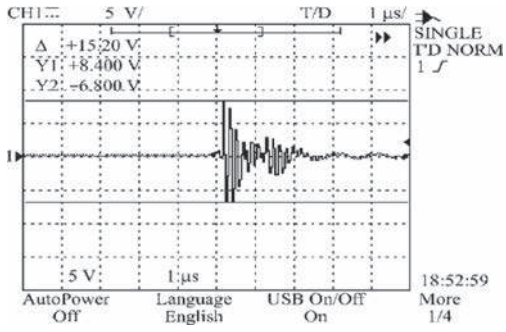

Figure 4. External circuits of the inverter to the motor segment electromagnetic interference test results.

4.3 *Changes of the disturbed data*

RAM memory can be written to the computer system, the interference signal against the lower RAM data can be tampered with, procedures and forms may remain in the program memory EPROM avoid this data is subject to interference and sabotage in the SCM system, But for the on-chip RAM, chip, plug-in RAM data are likely to be interfered change.

4.4 *The spectrum of the electromagnetic interference of the inverter is wide*

Below 1 200 MHz electromagnetic interference, with periodic electromagnetic interference in the 500 MHz bands below the 500 MHz have electromagnetic interference, the maximum frequency of 119 MHz, the value of 31.5 dBmV/m, more than 500 MHz electromagnetic interference is less than a 60 dBmV/m.

Inverter to the motor segments the strong external circuits' induction pulse signal interference. Electromagnetic interference on the line in the winch operation process, the test results is shown in Figure 4.

As can be seen from Figure 2, the drive to the motor segment external circuits induction pulse signal interference intensity of the peak-to-peak value of about 15 V, is a normal level of interference, because in the actual case, the section of cable is short, so the impact will not too large. Filter to the upper the feed switch long section of cable, strong interference.

According to the actual test results, winch drives and pumps, the rig starts to have a greater external circuits induced surge signal the Working Face Wind Tunnel probe by the winch drive and rig power cables, waist Lane probe by the pump start. Among them, the rig starts probe. When inverter and rig at the same time start to generate strong

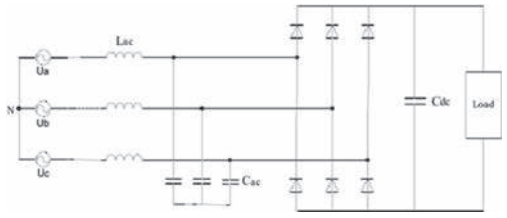

Figure 5. The three-phrase rectifier with LC filter installed in AC side.

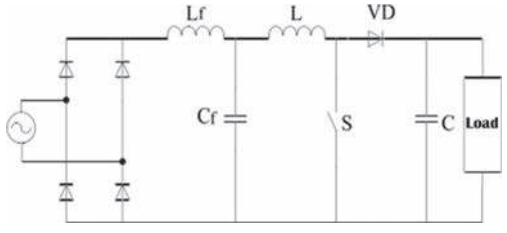

Figure 6. Single-phase PFC circuit based on Boost Convertor.

signal interference, leading to the phenomenon of false alarms in the probe.

Coal mine safety monitoring system alarm status, inspection in accordance with the order of the substation within the transmission channel one by one inspection, the inspection period and the number of sub-station on that channel, sub-stations, the more the longer the inspection cycle.

When the monitoring value is abnormal, the system changes its order of sub-stations inspection by inspection, increase the polling frequency of the sensor where the sub-station is, shorten the inspection period of the sub-station, while the substation inspection remains the same, repeatedly polling the sub-station within the specified time, if the monitored values returned to normal, this alarm is determined as a false alarm. (Shown in Figure 3).

The working process of the software in the coal mine safety monitoring system can be described as follows:

1. Receives sub-station data;
2. Analysis the completion monitoring by distinguishing the value of the alarm status is true or false by detecting the calibration of state, the change status or the duration.

ABSTRACT: In order to investigate the effect of coal particle size on gas desorption and diffusion law at constant temperature, the constant temperature dynamic coal particle gas adsorption and desorption experiment with different particle sizes was conducted in the coal gas adsorption and desorption experiment system. The results suggest that gas desorption laws of different particle size of coal samples show a good consistency at different pressures, and the cumulative desorption of gas coal particle is linear with time. For the same particle, the higher the initial pressure, the more the maximum gas desorption; the smaller the coal particle is, the more quickly the gas desorption rate is at the same initial pressure. Then, the gas spherical flow mathematical model is built based on Darcy law and is analysed with finite difference method. At last, the gas spherical flow mathematical model is constructed with Visual Basic. The contrast between numerical simulation and experimental results shows that the gas flow in the coal particle internal micropore accords with Darcy's law.

1 INTRODUCTION

In order to reveal the migration and diffusion law of gas in coal and describe the gas desorption and diffusion law accurately, the constant temperature dynamic coal particle gas adsorption and desorption experiment with different particle size was conducted in the coal gas adsorption and desorption experiment system. The gas emission is simulated and calculated with computer program developed by Visual Basic. The simulation results are compared with the experimental results. They provide the basis for the study of coal particle gas diffusion law and supply evidences for the further study of the gas emission law and gas outburst mechanism.

2 COAL GAS DESORPTION EXPERIMENT UNDER DIFFERENT PARTICLE SIZE

The coal gas isothermal adsorption and desorption experiment system mainly includes coal gas adsorption and desorption experiment system, data acquisition system, constant temperature system, weighing system and drying of degassing system. In order to investigate the effect of coal particle size on gas desorption and diffusion law at constant temperature, the coal samples were processed and selected in 4–4.75 mm, 1–1.2 mm, 0.425–0.55 mm and 0.2–0.25 mm, their numbers are $1^{\#}$, $2^{\#}$, $3^{\#}$ and $4^{\#}$. Then, the desorption experiments with the four coal samples were conducted at different pressure. The cumulative desorption amount variation curves of the four coal samples at four different initial pressures were plotted. The experiment data analysis shows that the cumulative desorption reciprocal was linear with time square reciprocal and R^2 was more than 0.99 (Qin Yueping, et al. 2012). The equation can be expressed as:

$$\frac{1}{Q} = \frac{1}{AB} \cdot \frac{1}{\sqrt{t}} + \frac{1}{A} \tag{1}$$

Equation (1) also can be expressed as:

$$Q = \frac{AB\sqrt{t}}{1 + b\sqrt{t}} \tag{2}$$

In the formula, Q is the cumulative desorption of gas (ml/g), T is desorption time (h), A and B are desorption constants.

The analysis suggests that gas desorption laws of different particle size has a good consistency at different pressure. At a given pressure, the gas desorption will increase and desorption rate will decrease with time. When time tends to infinity, desorption rate becomes close to zero. The smaller the coal particle is, the more quickly the gas desorption rate is, and the shorter the complete desorption time is. The analysis shows that desorption constant A depends on the initial pressure: the higher the pressure, the bigger A. B will increase with the decrease of particle size.

Due to space limitation, only the curves of cumulative desorption with time at 0.5 MPa, 1 MPa, 2 MPa and 4 MPa and the relationship curve of the cumulative desorption reciprocal with time square reciprocal are depicted here. They are showed in Fig. 1 and Fig. 2. Gas adsorption constants of the coal samples were obtained by experiment results. a is 26 m^3/t and b is 0.3 MPa^{-1}.

3 DIFFUSION MODEL OF COAL PARTICLES

Coal particle is a kind of porous media, so there are many factors influencing the gas emission in it. Several assumptions were made to simplify the problems and find out several main factors affecting the law of its radiation.

1. As an isotropic porous media, the porosity and permeability coefficient of the coal particle are not affected by the internal gas pressure change of coal particle (Zhou Shining 1957, Li Yunhao, et al. 2007).
2. Adsorption gas in coal grains was mainly considered but the free gas in the micropores in the process of analysis was ignored. Gas content can be expressed as:

$$Q = \frac{abp}{1+bp} \tag{3}$$

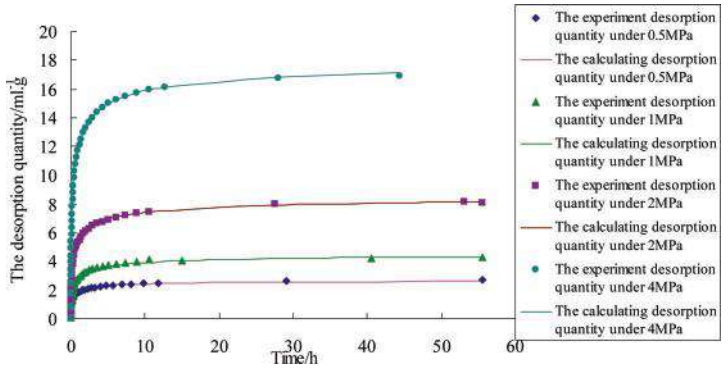

Figure 1. The curves of cumulative desorption with time at different pressure.

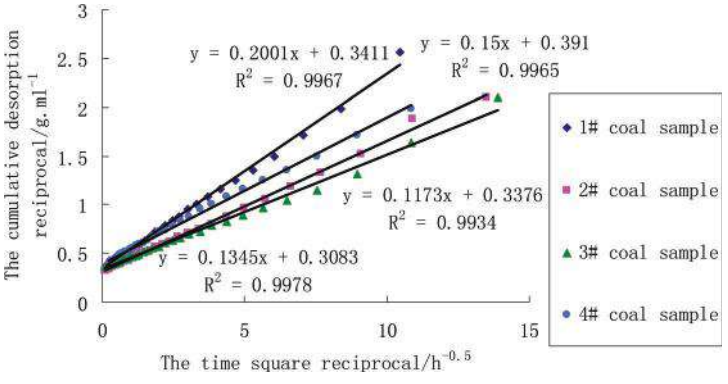

Figure 2. The relationship curve of cumulative desorption reciprocal with time square reciprocal of four coal samples at 0.5 MP.

In the equation, a, b are Langmuir adsorption constant (m^3/t, MPa^{-1}), p is the internal gas pressure of coal particle (MPa), Q is coal particle gas content of unit mass (m^3/t).

3. Temperature keeps invariant in gas diffusion process.
4. Changes of pressure and density of the gas meet the state equation of ideal gas.
5. The gas flow in coal is laminar flow, and in accordance with the Darcy's law (Tian Zhiwei 2010, Li Hongyan 2008, Yi Jun, et al. 2007, Hu Weiyue, et al. 2009, Yang Qingling, et al. 2007).

$$u = -\left(\frac{K_x}{\mu}\frac{\partial p}{\partial x} i + \frac{K_y}{\mu}\frac{\partial p}{\partial y} j + \frac{K_z}{\mu}\frac{\partial p}{\partial z} k \right) \tag{4}$$

In the equation, Kx, Ky, Kz are the coal seam permeability along the x, y, z direction respectively, μ is gas viscosity coefficient.

According to the law of mass conservation, in any control volume unit of the flow field of coal particle, the quality of inflow and outflow of the volume is equal to the increase of gas quality of control volume unit itself in dt (Zhou Shining & Sun Jizheng 1965).

$$\frac{\partial Q}{\partial t} = \nabla\left(\rho_g u\right) \tag{5}$$

In the equation, Q is gas content(m^3/t), t is time (s), ρ_g is gas density (kg/m^3), u is velocity (m/s), ∇ is Hamiltonian operator.

A finite difference method was used to calculate the model. The radius was divided into N segments by each node from the center to the surface, which is showed in figure 3; the node numbers are 0, 1, 2…N. Considering the variation of parameters such as pressure, gas content, seepage velocity and so on in the center of sphere was less than in the spherical near, the node space used equal ratio change and decreased gradually from the center of sphere to spherical. The whole coal briquette can be divided into several spherical shells and one center ball when the middle of the two adjacent nodes seems to be the concentric sphere.

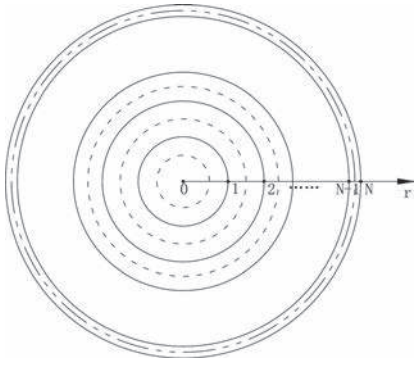

Figure 3. The dividing schematic diagram of pitch points under spherical coordinate system.

The difference equations can be established by changing derivative into difference quotient according to the above differential equation, also it can be built by using the law of mass conservation according to the balance of the quality of the spherical shell as showed in figure 3. Here's a brief analysis of the process of creating difference equation using the law of mass conservation.

In addition to spherical shell of center ball and the node N of outer surface, all interior and exterior surface of spherical shells are the center of the sphere between two nodes. The gas flow velocity and flow rate of each spherical shell surface can be represented by the pressure between two nodes according to Darcy's law.

Spherical shell i contains a node i. The gas quantity lateral flowing into the spherical shell can be expressed in formula (6) (Zhou Shining 1983, Qian Jin, et al. 2010).

$$K\frac{\left(\frac{P_{i-1}^n - P_i^n}{2} + \frac{P_{i-1}^{n-1} - P_i^{n-1}}{2}\right)}{r_i - r_{i-1}} \times 4\pi\left(\frac{r_{i-1} + r_i}{2}\right)^2 \tag{6}$$

The gas quantity flowing out the lateral of spherical shell can be expressed in formula (7).

$$K\frac{\left(\frac{P_i^n - P_{i+1}^n}{2} + \frac{P_i^{n-1} - P_{i+1}^{n-1}}{2}\right)}{r_{i+1} - r_i} \times 4\pi\left(\frac{r_{i+1} + r_i}{2}\right)^2 \tag{7}$$

The gas desorption quantity in spherical shell in unit time can be expressed in formula (8).

$$\frac{4}{3}\pi\left[\left(\frac{r_{i+1} + r_i}{2}\right)^3 - \left(\frac{r_{i-1} + r_i}{2}\right)^3\right] \times \frac{ab\rho}{2\left(1 + b\sqrt{\frac{P_i^n + P_i^{n-1}}{2}}\right)^2\sqrt{\frac{P_i^n + P_i^{n-1}}{2}}} \frac{P_i^n - P_i^{n-1}}{\Delta t} \tag{8}$$

In the equation, subscripts i – 1, i and i + 1 are the node number and the superscripts n-1 and n are the time node number, Δt is the n-th time step. The differential equation of gas unsteady flow in coal globe based on mass conservation is expressed in formula (9).

$$k\frac{\left(\frac{P_i^n-P_{i+1}^n}{2}+\frac{P_i^{n-1}-P_{i+1}^{n-1}}{2}\right)}{r_{i+1}-r_i}\left(\frac{r_{i+1}+r_i}{2}\right)^2 - k\frac{\left(\frac{P_{i-1}^n-P_i^n}{2}+\frac{P_{i-1}^{n-1}-P_i^{n-1}}{2}\right)}{r_i-r_{i-1}}\left(\frac{r_{i-1}+r_i}{2}\right)^2 = \frac{1}{3}\left[\left(\frac{r_{i+1}+r_i}{2}\right)^3-\left(\frac{r_{i-1}+r_i}{2}\right)^3\right] \times \frac{ab\rho}{2\left(1+b\sqrt{\frac{P_i^n+P_i^{n-1}}{2}}\right)^2\sqrt{\frac{P_i^n+P_i^{n-1}}{2}}} \frac{P_i^{n-1}-P_i^n}{\Delta t} \quad (i=1,2,\&,N-1) \tag{9}$$

The partition control body of 0 node is spherule, rather than spherical shell. Its differential equation is expressed in formula (10).

$$k\frac{\frac{P_0^n-P_1^n}{2}+\frac{P_0^{n-1}-P_1^{n-1}}{2}}{r_1}\left(\frac{r_1}{2}\right)^2 = \frac{1}{3}\left(\frac{r_1}{2}\right)^3\frac{ab\rho}{2\left(1+b\sqrt{\frac{P_0^n+P_0^{n-1}}{2}}\right)^2\sqrt{\frac{P_0^n+P_0^{n-1}}{2}}}\frac{P_0^{n-1}-P_0^n}{\Delta t} \tag{10}$$

According to the boundary conditions, when r is equal to R, P is equal to P_w, so the relationship between P_N and P_W is showed in formula (11).

$$P_N = P_w \tag{11}$$

So the complete equation set which makes N node pressure squares of the n moment as unknown quantity is formed by formula (9), formula (10) and formula (11). The pressure of next moment can be calculated when one time step and the pressure of last moment are given. From this the gas pressure in coal globe at any time can be calculated. Considering the gas emission rate will decrease with time, the equal ratio time step is used in the calculations and is increased gradually. In this way, time can be saved while ensuring the accuracy.

On the right-hand side of formula (9) and formula (10) are nonlinear expressions of node pressure squares of the n moment, so iterative method should be used. The number under radical sign should be calculated when $P_i^n = P_i^{n-1}$, was set. In this way quasilinear system of equations and a group of solutions are obtained, then the number under radical sign is calculated with the solution, once again new quasilinear system of equations and a new group of solutions are obtained. The final result will be attained until the relative error of two computing solutions is less than a small value.

The coal desorption gas quality in Δt can be calculated with formula (12) after the gas pressure square is obtained.

$$\Delta Q = k\frac{P_{N-1}^n-P_N^n}{r_N-r_{N-1}}\times 4\pi R^2\Delta t \tag{12}$$

The coal cumulative desorption gas is the sum of desorption quantity at any time-point.

4 PROGRAM DESIGN

In order to avoid conversion between units in the process of operation, several dimensionless numbers are used.

The dimensionless radius:

$$X = \frac{r}{R} \tag{13}$$

The dimensionless pressure:

$$Y = b^2P \tag{14}$$

The dimensionless time:

$$T\frac{tk}{\rho aR^2b^2} \tag{15}$$

The dimensionless desorption dimensionless number:

$$M_L = \frac{Q}{a\rho R^3} \tag{16}$$

Gas flow equation of coal particles dimensionless:

$$\Delta T\frac{Y_i^n-Y_{i+1}^n}{X_{i+1}-X_i}\left(\frac{X_{i+1}+X_i}{2}\right)^2 - \Delta T\frac{Y_{i-1}^n-Y_i^n}{X_i-X_{i-1}}\left(\frac{X_{i-1}+X_i}{2}\right)^2 + \frac{1}{3}\left[\left(\frac{X_{i+1}+X_i}{2}\right)^3-\left(\frac{X_{i-1}+X_i}{2}\right)^3\right] \times \frac{1}{\left(1+\sqrt{\frac{Y_i^n+Y_i^{n-1}}{2}}\right)^2\sqrt{\frac{Y_i^n+Y_i^{n-1}}{2}}}Y_i^n = \frac{1}{3}\left[\left(\frac{X_{i+1}+X_i}{2}\right)^3-\left(\frac{X_{i-1}+X_i}{2}\right)^3\right] \times \frac{1}{\left(1+\sqrt{\frac{Y_i^n+Y_i^{n-1}}{2}}\right)^2\sqrt{\frac{Y_i^n+Y_i^{n-1}}{2}}} - Y_i^{n-1} - \Delta T\frac{Y_i^{n-1}-Y_{i+1}^{n-1}}{X_{i+1}-X_i}\left(\frac{X_{i+1}+X_i}{2}\right)^2 - \Delta T\frac{Y_{i-1}^{n-1}-Y_i^{n-1}}{X_i-X_{i-1}}\left(\frac{X_{i-1}+X_i}{2}\right)^2 \tag{17}$$

The difference equation dimensionless of control volume in 0 node is showed as formula 18.

$$\Delta T \frac{\frac{Y_0^n - Y_1^n}{2} + \frac{Y_0^{n-1} - Y_1^{n-1}}{2}}{X_1} \left(\frac{X_1}{2}\right)^2 = \frac{1}{3}\left(\frac{X_1}{2}\right)^3 \frac{1}{2\left(1+\sqrt{\frac{Y_0^n + Y_0^{n-1}}{2}}\right)^2 \sqrt{\frac{Y_0^n + Y_0^{n-1}}{2}}} \left(Y_0^{n-1} - Y_0^n\right) \tag{18}$$

The boundary condition is $Y_w = b^2 P_w$ when $X = 1$ and $Y_N = Y_w$.

The gas dimensionless desorption in Δt is formulation 19.

$$\Delta M_L = \Delta T \frac{Y_{N-1}^n - Y_N^n}{X_N - X_{N-1}} 4\pi \tag{19}$$

A computer program is developed with Visual Basic based on finite difference calculation model and its corresponding boundary conditions. The program structure diagram is showed in Fig. 4 (Zhou Shining 1983).

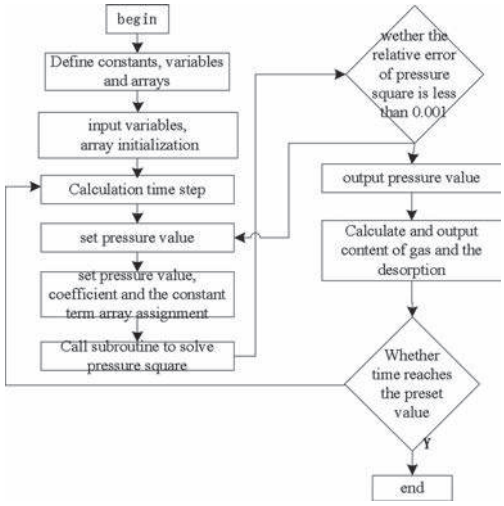

Figure 4. Flowchart of program structure.

5 COMPARATIVE ANALYSIS OF CALCULATION AND EXPERIMENTAL RESULTS

The coal particle radius is 0.27 mm and its permeability coefficient is 1×10^{-5} m^2/(MP^2 · s). Gas adsorption parameters are obtained by analyzing the experimental results. a is 27.32 m^3/t, b is 0.35 MPa^{-1} and the coal density is 1.2 m^3/t. The gas flow equation is calculated with the program designed by VB based on the experimental parameters and the dimensionless cumulative desorption of gas is obtained. Then the dimensionless time and the dimensionless cumulative desorption are translated into dimension time and dimension cumulative desorption.

In order to comparatively analyze the simulation and experimental cumulative desorption, they are transformed into desorption quantity of unit mass of coal. The results are obtained by finely adjusting the permeability coefficient and a of coal particles, as shown in Fig. 5 and Fig. 6.

Fig. 5 shows that simulation by the gas flow equation under spherical coordinates and experimental cumulative desorption has a high fitting degree. Moreover, neither the simulation nor the experimental cumulative desorption confirms that the reciprocal of accumulated desorption quantity and time square has a good linear relationship at external pressure remaining unchanged. This affirms that the gas inside the coal particle flow in the micro pore accords with Darcy's law.

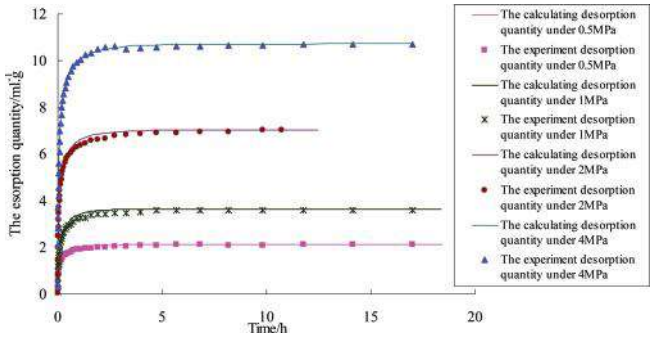

Figure 5. The simulation and experimental desorption of 4# coal sample at different pressure.

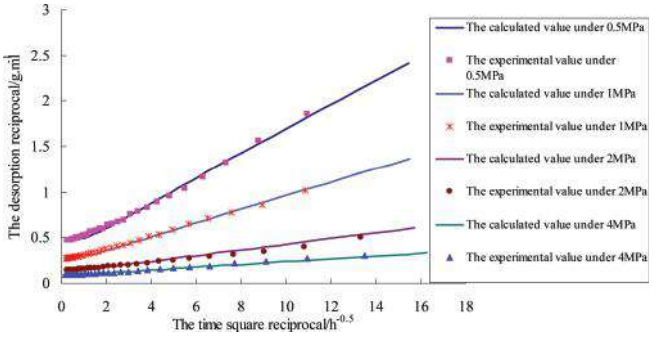

Figure 6. The relationship between desorption quantity reciprocal and time evolution reciprocal of 4# coal sample.

6 CONCLUSION

1. The change curve of cumulative desorption of coal sample at four different initial pressure along with time is obtained by dealing with experiment data of constant temperature desorption. The result shows that the reciprocal of accumulated desorption quantity and time square have a good linear relationship. Empirical formula of gas desorption laws is simulated and the physical meaning of each parameter is analyzed.
2. The radiation model of the radial methane flow in spherical coal grains is established and is calculated with finite difference method based on mass conservation law and Darcy's law and the mathematical model is non-dimensionalized. The coal particle gas diffusion equation is calculated with computer program developed with VB.
3. Simulation computation is performed with the basic parameters of the experimental coal sample. By contrast, the simulation results accord with the experimental very well. It confirms that the gas flow in the coal particle internal micropore accords with Darcy's law.

Research on heat damage control and combined technology of waste heat utilization

Jie Ma
North China Institute of Science and Technology, Beijing, China

ABSTRACT: This thesis analyzes the heat damage control and researches the combined technology of heat pump and cooling for waste heat utilization based in Zhujixi Coal Mine in Anhui Province. The combined technology is to fully recover waste heat, convert high-level heat damage into heat supply resource for coal mine. Thus it can lower underground cooling load and operating cost, replace boiler heat source with recovered energy and achieve energy conservation and emission reduction.

1 INTRODUCTION

In coal-mining site, huge heat energy consumption is needed for ground building heating, shaft protected from cold and hot water using in worker's bathroom. Traditionally, the heat energy is provided by coal-fired boilers, which leads to serious pollution as well as large consumption of energy.

High temperature damage is one of the top five mine disasters (W Wen et al. 2002). The main sources of heat dissipation include rock high temperature and great air compression heat from in-depth mining, heat release of geothermal water, coal oxidation, machine and lighting equipment, human heat and so on. Heat damage control requires great investments and system operation needs huge energy consumption. Statistics of large mine cooling systems at home and abroad show that energy consumption of the cooling systems accounts for 15%–20% of that from production systems (W Xiujun & H Chunsheng 2007). In addition, drainage and ventilation in high temperature mines have a relatively high temperature and remain constant in all seasons. Such low-level heat energy is greatly stored in the mines and has been released into the atmosphere instead of been applied.

Researches from home and abroad are mainly focused on heat damage control and heat damage utilization separately at present. Although China University of Mining & Technology makes a lot of researches on them, the combination of both are still not available. This thesis presents a combined tech-nology of heat pump and cooling based on Zhujixi Coal Mine in Anhui Province. Heat pump system is used to convert high-level heat damage into heat supply resource for coal mines, which could replace traditional boilers in winter; while in summer the combined technology could help offer hot shower water, cool incoming air flow, and lower underground cooling load. The paper also designs an overall plan for heat damage control and waste heat utilization, which optimizes the systems and takes the facilities, equipment and pipelines into consideration to lower investments and operating costs.

2 UNDERGROUND COOLING AND HEAT BALANCE OF HEAT UTILIZATION

Summer: draw incoming air flow heat through the heat pump and supply it for shower water, while take excessive heat through mine ventilation. After being precooled and dried, the incoming air flow has a relatively low temperature and humidity, as well as strong moisture absorption and cooling ability which could prevent such underground heat damages as heat dissipation from wall rock and hot water. For heat damages that could not be removed through air flow, cooling units are applied in the shaft and the condensation heat is discharged through cooling tower or return air flow. Since the mine air flow has been precooled, it would reduce cooling units load in the shaft and its operating time.

Meanwhile, part of heat pump units draw heat from buildings to be supplied for air-conditioners. The drawl waste heat could be carried away through mine ventilation or drainage. See Figure 1 for heat balance.

Transition seasons: Waste heat recovery system is given priority according to the underground temperature. Recover the waste heat of mine total return air and supply it for hot shower water. When cool energy is needed under the shaft, the heat

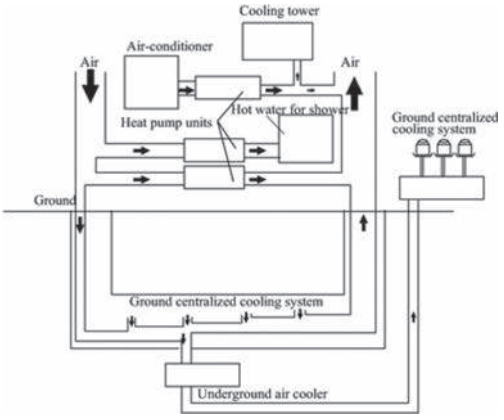

Figure 1. Heat balance in summer.

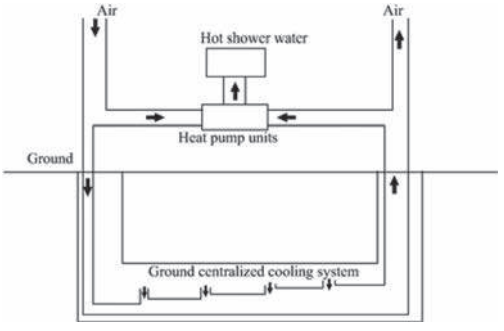

Figure 2. Heat balance in transition seasons.

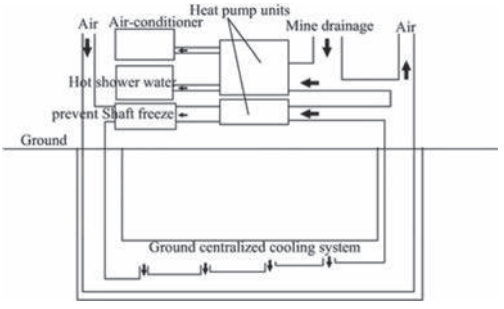

Figure 3. Heat balance in winter.

from mine incoming flow is recovered and then is provided for shower water. See the Figure 2 for the heat balance.

Winter: Since the Zhujixi Coal Mine is of high temperature, huge heat energy is stored in its total return air and mine drainage. In consideration of the relatively large total return air, the plan prefers to apply waste heat system to recover the waste heat of total return air, to provide heat for pithead antifreezing, shower hot water and building heating. See the Figure 3 for the heat balance.

3 CALCULATION OF INLET AIR FLOW COOLING HEAT OF WASTE HEAT UTILIZATION

In summer heat pump systems are used to draw heat from mine incoming air flow for shower water and at the same time air flow is precooled and dried. During the hottest summer days at least four heat pump units run to cool mine incoming air flow in Zhujixi Coal Mine. The cooling capacity provided by these 4 units reaches up to 4400 kW whose influence on the temperature of incoming air flow is calculated.

Incoming air quantity in pithead of auxiliary shaft: 400 m^3/s.

Dry-bulb temperature calculated outside air-conditioning room in summer: 35.6°C.

Wet-bulb temperature calculated outside air-conditioning room in summer: 28.1°C.

The relative humidity of mine incoming air flow in hottest summer days is 57%, and h_1 (the enthalpy of incoming air flow) is 89.81 kJ/kg.

$$Q = \rho V (h_1 - h_2) = (89.81 - h_2) \times 400 \times 1.01 = 4400 \text{ kW}$$

$h_2 = 78.92$ kJ/kg

H_2-the enthalpy of incoming air flow after cooling treatment

Consulting the psychrometric chart with the same relative humidity, it is found that the temperature of incoming air lowers by 3 °C under the condition that the incoming air temperature is 32.8°C and 77% air contains 83.20 kJ/kg of enthalpy. That could effectively reduce the underground heat damage.

4 RECOVERABLE WASTE HEAT CAPABILITY IN HIGH TEMPERATURE MINE WITH HEAT DAMAGE

4.1 *Calculation of mine drainage waste heat*

According to geological exploration data and field survey of Zhujixi Coal Mine, the mine drainage water volume reaches 150 m^3/h. Underground cooling measures are taken in this coal mine and the water temperature is above 32°C. Considering the working capacity of the current heat pump, the recoverable heat quantity could reach 4187 kW.

4.2 *Calculation of waste heat of mine total return air*

The temperature and humidity of mine return air are hardly affected by outdoor air temperature and remain constant all year around. The design air quantity in Zhujixi mine is at least 380 m^3/s. After measurement, the winter ventilation temperature is above 26°C and the relative humidity remains 95% all year around. Considering the technology of current heat pumps, the recoverable heat quantity could reach 26, 193 kW.

4.3 *The total quantity of recoverable waste heat*

The total quantity of recoverable waste heat is 30, 380 kW, equal to that produced by the 43-ton boiler. However, the maximum using heat is up to 15, 514 kW in winter in the mine, which is equal to that produced by the 22-ton boiler. Therefore boiler heat supply could be fully replaced through recovering the waste heat in high temperature mines like Zhujixi.

5 UNDERGROUND COOLING PLAN FOR ZHUJIXI MINE

In the late period of production in Zhujixi, eight tunneling places and two working faces are in operation and the total heat load in the shaft reaches 11, 000 kW. The plan designs the ground centralized cooling system and supplies water with large temperature difference, thus which can not only keep enough space for installed capacity in the shaft but also effectively reduce pipelines and pipe fittings that transmit refrigerants from ground to underground. See the underground cooling plan in Figure 4. In the ground centralized cooling system, the condensation heat goes through closed cycle cooling water and is directly emitted to the air through the cooling tower. Two cooling units are set up on the ground, each going through two-level cooling systems. The cooling unit at the first level is responsible for main cooling load; the design temperature of the incoming refrigerant water is 18°C, while that of the outlet water is 5°C. The cooling unit at the second level is less efficient and is responsible for remaining cooling load; the design temperature of incoming water is 7°C and that of the outlet water is 2.5°C (China Coal Construction Association 2007). The total cooling capacity at these two levels is 6000 kW.

The primary refrigerated water at the temperature of 2.5°C is transmitted to the underground cooling chamber through single circulating pump in the refrigeration room on the ground, then it is converted into secondary refrigerated water at the temperature of 6.5°C through the high and low pressure heat exchanger and is transmitted to each cool using point. At each point, cooling capacity is discharged through underground air cooler. The temperature difference of underground return water is considered to be 12°C.

6 WASTE HEAT UTILIZATION PLAN FOR ZHUJIXI COAL MINE

As showed in Figure 5, return air heat exchanger is installed on the total return air diffusion tower and it transfers huge heat from return air to circulation water by means of spray. As the low-temperature heat source of heat pump system (J Nengzhao 1997), the temperature of circulation water is lowered after the heat of it is drawn by the system. Finally, the circulation water is conveyed to the return air exchanger. The process goes on like that over again and again.

In winter, the recovered heat from return air through this system is supplied to building heating, shaft antifreezing and daily hot water (N Yongsheng & W Jianxue 2012).

In summer, the incoming air is cooled through the shaft antifreezing heat exchanger to lower the underground cooling load and to convert heat damages into heat energy for hot shower water.

In transition seasons, the heat that is recovered from mine return air or incoming air by the heat pump units is supplied to daily hot water.

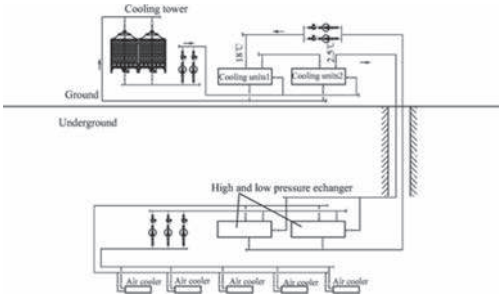

Figure 4. Ground centralized system flowchart.

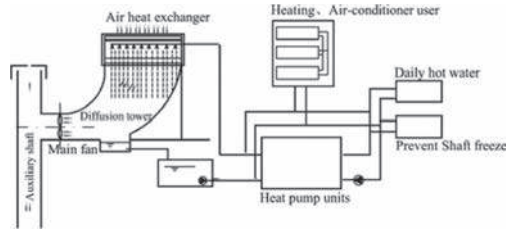

Figure 5. Return air heat exchange schematic diagram.

7 OVERALL PLANS OF UNDERGROUND COOLING AND WASTE HEAT UTILIZATION FOR ZHUJIXI MINE

The plan takes an overall consideration of heat damage control and waste heat utilization in Zhujixi Coal Mine, which optimizes the systems, uses complex facilities, shares the softened water treatment system and gives an overall consideration of cooling tower equipment and pipeline layout.

Complex facility is an integrated unit that combines underground cooling with the recovery and utilization of ventilation heat. The facility has two storeys and one auxiliary storey. It is 66 meters long and 22 meters wide and runs from south to north. In the first floor, there are electric room, underground cooling room and chemical water room from east to west. The height of the first floor is 7 m. In the second floor, there are electric room, heat recovery room and impounding trunk for shower water from east to west. The height of this floor is 5 m. In the auxiliary floor there are staircases and some offices and the height of this floor is 3 m. The second floor roof plane has an elevation of 12.00 m and it is mainly for the cooling tower collecting pool which combines the underground cooling system with mine ventilation heat recovery and utilization system. The mechanical cooling tower is erected upon the collecting pool. The auxiliary floor roof plane has an elevation of 15.00 m and is equipped with water tank on the top.

The production pool, pump room, raw water decontamination plant and other auxiliary production buildings are located in the south of the complex facility; the soften water tank lies in the southwest corner of complex facility. Piping rack is mainly used for erecting refrigerant pipes and it stretches along the road to the gangue shaft and main shaft. Two refrigerant pipes starting from the underground cooling room of the complex facility could easily reach the gangue shaft and the main shaft and extend to the underground. The cold and hot water pipes from the heat pump room of the complex facility could also be laid out along the roads in the mine area.

8 CONCLUSION

1. Present the heat quantity balance pattern in winter and summer for underground cooling and heat utilization.
2. Analyze the influence of waste heat utilization on incoming air cooling capacity and on waste heat capacity of high temperature heat damage.
3. Put forward the overall plan of mine heat damage control and waste heat utilization for Zhujixi Coal Mine, which optimizes the systems and takes the complex facility, equipment and pipelines into consideration.

To sum up, based on the Zhujixi Coal Mine of Anhui Province, this paper combines heat pump technology and underground cooling technology and then converts high temperature heat damages into heat supply so as to lower the underground cooling load as well as to replace traditional boiler heat source with heat recovery and utilization. All achieves the goal of energy conservation, emission reduction and less investment.

Research on mine refrigeration of large mines with large mining depth

Yongsheng Niu
China University of Mining and Technology, Beijing, China
North China Institute of Science and Technology, Beijing, China

Jianxue Wang
Beijing CUMT Energy Conservation Technology Co., Ltd., Beijing, China

ABSTRACT: Zhujixi coal mine is a typical large mine characterized with large mining depth, high ground temperature, large heat dissipation from electromechanical equipment and serious heat damage. This paper takes Zhujixi coal mine as an example and puts forward ground two-stage refrigeration, large temperature difference to supply cooling as well as the adoption of high-low pressure heat exchanger to overcome high hydrostatic pressure. Those solutions solve the problem of difficult heat removal in high temperature mine and of high hydrostatic pressure in large mining depth mine. In addition, it suggests applying domestic equipment to underground cooling from the point of economic benefits.

1 INTRODUCTION

With the increase of mining depth and the continuous enhancement of mining mechanization, high temperature heat damage of mine in China has become more prominent. According to the ground temperature observation data of our country in coal field, the average rising rate of ground temperature (geothermal gradient) in coal mines is up to 2–4°C/hm (1 hm = 100 m) (W Xiujun. & H Chunsheng 2007). Most high temperature mines (about 90%) are deep mined and the rock temperature is very high there.

In *The Safety Regulations for Coal Mine* it is explicitly stipulated that the air temperature should be no higher than 26°C in mining face or 30°C in electromechanical chamber. Mining must be stopped if the air temperature respectively exceeds 30°C and 34°C in the above-mentioned two places (The State Bureau of Safe Production Supervision and Administration & State Administration of Coal Mine Safety 2011).

Zhujixi coal mine is located in Panji area and the expected production capacity is 4 million tons per year. The horizontal elevation of the coal mine is –960 meters in height, while in the constant-temperature zone its depth is 30 meters, its temperature is 16.8°C, its average geothermal gradient is 2.78°C/hm and the ground temperature in horizontal working face is over 43.49°C. All above demonstrate it a typical high geothermal mine. According to the forecast of underground meteorological environment, there will be a working environment in some parts of working face where the temperature will be over 36°C and the relative humidity will be 97% or more, which far exceeds the rules in *The Safety Regulations for Coal Mine*. Therefore, the underground cooling must be carried on.

In order to reasonably, effectively and economically lower the temperature in the working face and to fully utilize the technology of mining, ventilation and cooling at the same time, artificial refrigeration measures must be taken to improve the underground working environment, to protect miners' health and to improve labor productivity.

2 COOLING LOAD ANALYSIS OF UNDERGROUND REFRIGERATION IN ZHUJIXI COAL MINE

The thermal environment of mine is affected by many factors and dominant factors among them are summarized as follows.

2.1 *Ground atmospheric environment*

Air current of mine is carried from the ground into the underground, so the ground atmospheric environment has a great influence on the meteorological conditions of underground air current. Located in the alluvial plain of the Huaihe River, Zhujixi coal mine belongs to temperate sub-humid monsoon climate, has obviously seasonal characteristics and is extremely hot in summer. According to the meteorological observation statistics of 10 consecutive years from the weather station in Fengtai county nearby, the average temperature

is 19.3°C and the relative humidity is 70.9% and the atmospheric pressure is 101, 160pa in April, while they correspondingly are 31.9°C, 81.8% and 100, 091pa in July when it is hottest among hotter months from June to September. Air inlet from ground is a bit higher both in temperature and in humidity in summer, which leads to underground at a higher temperature and humidity.

2.2 *Geology and geothermal environment*

The observation well data from Jiulonggang of Huainan is recorded that the depth is 30 meters and the temperature is 16.8°C in constant temperature zone. Because its geothermal gradient is 2.44–3.01°C/nm (one single hole) and the average is 2.78°C/hm, the geothermal gradient of temperature hole in Zhujixi coal mine is at the normal geothermal gradient range within which there exists a high-temperature area in the medium-deep part of the zone. The primary high temperature zone (31°C or above) generally lies under –504 to –630 meters and the secondary high temperature zone (37°C or above) under –701 to –880 meters.

2.3 *Production environment of mine*

The production environment of mine during mining has a direct influence on the underground thermal environment from heat sources such as heat from high temperature palisades, heat from electromechanical equipment during operation, heat release in transportation of coal and gangue, compression heat from ventilating air and heat from oxidation in extracting bare rock and coal (W Wen et al. 2002). All makes heat exchange with the mine air current occur and finally causes the underground temperature to rise.

2.3.1 *Heat dissipation from high temperature palisades and rib*

The coal seam of Zhujixi coal mine is deep buried and ground temperature is high, so a lot of terrestrial heat is conveyed to ventilating air underground at the form of radiation and ventilating convection through the high temperature palisades and rib. This is an important factor to cause the high temperature underground.

2.3.2 *Heat dissipation from electromechanical equipment during operation*

Zhujixi coal mine is intensively exploited and it is operated by means of machines in mining, excavating and transporting. Besides, the installed capacity of electromechanical equipment is larger. The production capacity of fully mechanized coal face is 1.0 Mt/a~4.0 Mt/a and its installed capacity is 6000 kW ~ 7000 kW.

The average power of ordinary excavating face is 200 kW and that of fully mechanized coal face is 350 kW in coal roadway.

2.3.3 *Heat release in transportation of coal and gangue*

The temperature of coal and gangue falling from coal face is close to the initial temperature of surrounding rocks. Coal and gangue transfers their own heat to the air current during the process of transporting them to the ground, which causes the rising of temperature of air current.

2.3.4 *Compression heat from air current*

Zhujixi coal mine is deep mined, whose first level elevation is 780 meters and second level elevation is 950 meters, so the air current temperature largely rises out of its own natural compression.

2.3.5 *Heat release from oxidation*

Most coal seams of Zhujixi coal mine is easily self-ignition. Coal and surrounding rock containing coal and sulfur release heat from oxidation so it is also the heat source of local temperature rising.

2.3.6 *Heat from occupants*

There are 25 people in coal roadway, 17 people in rock roadway and 40 people in coal face.

Considering the above factors, the cold load statistics of underground cooling for Zhujixi coal mine is shown in the following table:

It can be clearly known the cooling demand of Zhujixi coal mine from the above table. They are respectively the heading during construction period, one stope face in startup, 2 working faces during production and one heading in production tail. Therefore, the scale of installed equipment for underground cooling is determined by the cooling load demand of production tail.

3 UNDERGROUND COOLING SCHEMES

3.1 *Options of refrigeration*

There are mainly two options to underground cooling among all. One is non-mechanical cooling method, namely strengthening the ventilation of mine, In general, heat damage can be coped with through strengthening ventilation under the circumstance when the ground temperature is 35°C below (H Hanhua 1997). Another is mechanical cooling method that is to condition the air of underground working environment. Target temperature cannot be reached solely by means of ventilating enhancement when the ground temperature reaches 35°C or above, so mechanical cooling method must be adopted. The low temperature of

Zhujixi coal mine reaches 43.49°C or above, which far exceeds the restricted temperature of 35°C, so mechanical cooling is a must.

Owing to different positions of refrigerating machines, there are usually three refrigerating modes such as mobile underground local cooling, underground centralized cooling and ground concentrated cooling.

3.1.1 *Mobile underground local cooling*

If heat damage is not very serious and individual temperature exceeds the limitation, local mechanical cooling measures can be taken to improve the meteorological conditions in coal face (W Wen et al. 2002).

The heat damage in Zhujixi coal mine is serious. The condensing heat is difficult to exhaust if mobile underground cooling is selected. According to recent data of high temperature mine, the return current temperature in mine could be over 32°C. If using return current to refrigerate, the refrigerating capacity of refrigerating machines will badly decline and the expected cooling effect cannot be met at the same time. Therefore, this refrigerating machine cannot be readily chosen for Zhujixi coal mine.

3.1.2 *Underground centralized cooling*

Underground centralized system refers to setting the condensing cooling device-cooling tower on the ground, while what is set up underground are refrigeration host, circulating water pump house, terminal air cooler device and pipe system.

Underground centralized refrigeration equipment is very expensive since this equipment can only be available in abroad markets at present. In spite of this, it needs anti-explosion protection for electrical and control equipments. Therefore, it is not economic to choose this mode. Besides, the total capacity of installable refrigerating units is finite because of the limited installed space in the underground cooling chamber. In all, this scheme is not recommended to adopt.

3.1.3 *Ground concentrated cooling*

This refrigeration method is to set underground refrigeration host and cooling water system & equipments in ground refrigerating station while to allocate cold-exchanging room, circulating water pump house, terminal-device air cooler and piping system underground. Refrigerant water is conveyed to underground through heat-insulted pipes and air current is cooled by air cooler.

Although Zhijixi coal mine is over 900 meters in vertical depth, there must be coupling devices and high-low pressure heat exchanging device for ground central air-conditioning system if the depth of mine is over 600 meters in the base of *Regulations of Mine Design in Coal Industry*. In addition, these devices can be made in China currently.

Ground concentrated cooling, which is not only safe and reliable but also convenient to refrigerate and to install and maintain equipments, can meet the cooling demand requirement of production tail in Zhujixi coal mine. Besides, all related equipments can be purchased in china. This scheme is recommended for the advantage of low unit investment, high efficient system and good underground cooling effect.

3.2 *Refrigerating parameters*

According to *Regulations of Heat Damage Prevention Underground Coal Mine,* the temperature of outlet water from refrigerator should not be higher than 3°C when ground concentrated cooling mode is put into practice.

The determination of refrigerating parameters not only is closely related to also affect the equipment selection. Low outlet water temperature from refrigerator is easy for the primary and secondary system to adopt domestic indirect exchange method at the advantage of reducing the engineering investment and dehumidification underground dehumidification. Big temperature difference from outlet and inlet of refrigerant water can reduce the circulation of refrigerant water in system, the volume of water-transmitting equipment and the operation cost.

Therefore, outlet water temperature is designed to be 2.5°C and return water temperature be 18°C in the ground concentrated refrigerating station.

3.3 *Underground cooling process*

As shown in figure 3.1 of ground concentrated cooling, the condensing heat is directly emitted to the atmosphere by means of the closed circulating cooling water through the cooling tower and on the ground there are two refrigerating units each of which works by two-stage refrigeration. Primary electrical refrigerating units are responsible for the main cooling load, of which the refrigerant water inlet temperature is designed to be 18°C and the outlet temperature is 5°C. Owing to its low-efficient cold working secondary electric refrigerating units deal with the remaining cooling load and the water temperature of inlet and outlet is respectively 7°C and 2.5°C. The total refrigerating capacity of the two stages is 6000 kW.

The primary chilled water of 2.5°C is conveyed to underground cooling chamber through the primary circulating pump in the ground refrigerating machine house and then is exchanged to the secondary chilled water of 6.5°C through high-low pressure heat exchanger. Finally the treated water

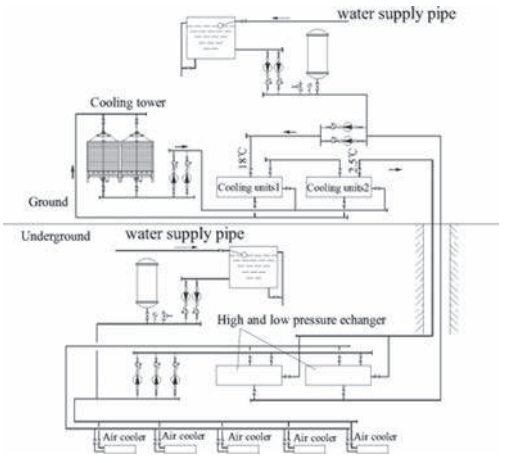

Figure 1. Flow chart of ground concentrated system.

is transported to each cooling spot where water is refrigerated by underground air cooler. The underground backwater temperature difference is designed to be 12°C.

3.4 *Construction of refrigerating machine room*

It is known from the cooling demand of the whole period in Table 1 that the cooling load fluctuation of Zhujixi coal mine during refrigeration is divided into two phases: smaller cooling load in construction period and startup time and larger cooling load in early production and production tail. Therefore, the construction scale of ground refrigerating house can be made by stages. Two 6000 kW refrigerating units are constructed in production tail instead of one unit to meet the cooling demand because the cooling capacity of ground concentrated cooling is required to reach 7650 kW in the early production. This paper suggests constructing two 6000 kW refrigerating units simultaneously and reserving adequate space for expanding one 6000 kW refrigerating unit.

3.5 *Layout of underground cooling chamber*

The layout of underground cooling chamber needs to take high-low pressure heat exchanger and secondary circulating pumps into account. Secondary water is neither constant pressure device nor pump power distribution.

Two sets of high-pressure heat exchanger whose heat transfer ability is up to 10 MW are suggested in order to leave enough room for future expansion in limited space.

Secondary circulating pumps are designed to be controlled by variable frequency and three pumps

Table 1. Cooling load table of underground refrigeration.

No.	Title of cooling face	Refrigerating capacity (kW/face)	Qty of faces (Face (pcs))	Total refrigerating capacity of all faces (kW)
1	Construction period			4500
1.1	Heading	750	6	4500
2	Startup time			5900
2.1	Heading	750	6	4500
2.2	Stope face	1400	1	1400
3	Early production			
3.1	Heading	750	6	4500
3.2	Stope face	1400	2	2800
4	Production tail			
4.1	Heading	750	8	6000
4.2	Stope face	2400	2	4800

like this will be collocated, two of which are put into operation and one for reservation to adapt themselves to the lift out of flow changes of secondary system operation which results from the difference of cooling supply in early production and production tail.

Constant pressure water inlet device and filter device are built up at a time in secondary circulating water system.

3.6 *Design of chilled pipeline system under mine*

Chilled pipelines are installed along the main entry and the cooling pipes are set in the crossheading of sealing tape machine in stope face.

The main pipes of underground chilled ducts are connected by flange and fast connectors are used at the end, which is easy for pipes to be dismounted with the advance of coal mine.

It is necessary to uniformly take the ducts of watering and air-pressing into consideration to determine the installed location of chilled pipelines in roadway. In the principle of convenience for traffic, pedestrians and installation & maintenance, special makers should be periodically made on the pipe so as to easily distinguish and manage pipes.

According to *Regulations of Heat Damage Prevention Underground Coal Mine,* it is appropriate if the flow velocity of chilled pipelines is 1.9–2.5 m/s (China Coal Construction Association 2007) and duct pressure should design to be 4.0 MPa based on which to decide the wall thickness of chilled pipes.

3.7 *Terminal equipments of underground cooling*

3.7.1 *Arrangement of air cooler in the driving face*

Air cooler is advised to be set in a place of driving face where it is less than 100 m far away from inlet tunnel air cooler at the opposite direction. Air cooler moves forward with the advance of heading and it moves once every 100 m advance.

Overcoming the resistance of air cooler should be considered in selecting the type of local driving fan because air cooler is not motivated by itself. Metal hose is adopted to connect air cooler water pipes with main pipe of refrigerant water.

3.7.2 *Arrangement of air cooler in stope face*

Air cooler in stope face is advised to set in the crossheading of belt and it is divided into pre cooling air cooler and face-cooling air cooler based on purpose. Pre cooling air cooler is responsible to eliminate the heat load occurring along the belt crossheading to precool the intake in stope face while face-cooling air cooler is to eliminate the heat load gained along the stope face to cool it.

The paper suggests selecting such an air cooler whose parts can be alternatively used and cooling exchange capacity is up to 400 kW since this device is always moved around.

The face-cooling air cooler is designed to arrange in the crossheading of belt machine where it is less than 100 m away from the coal face. The cooler must move back at intervals with the processing of extraction in coal face.

4 CONCLUSIONS

1. This paper analyses the environment of cooling load in underground cooling and the characteristics of heat damage in Zhujixi coal mine.
2. According to the analysis of common refrigerating methods for underground cooling, this paper recommends to apply ground concentrated cooling method to Zhujixi coal mine based on the characteristics of heat damage and determines the refrigerating parameter for cooling at the same time.
3. This paper puts forward the ground concentrated cooling process in Zhujixi coal mine and confirms the scale of ground refrigerating station, the layout of underground chamber, underground chilled pipelines and terminal cooling equipments.

To sum up, this paper makes a research on the typical high-temperatured Zhujixi coal mine whose depth is more than 900 meters and heat damage is serious. It not only puts forward the adoption of concentrated two-stage refrigeration on the ground and the high-low pressure heat exchanger to solve the problem of high hydrostatic pressure in large mining depth mine, but also suggests using domestic equipments to overcome the underground heat damage of similar mines.

Application feasibility study of single based station CORS in deformation monitoring of mine slope

Q.B. Wei, W. Li, L.B. Gao & C. Wang
University of Science and Technology Liaoning Civil Engineering Academy, Anshan, Liaoning, China

Q.L. Li
Shenyang Longtian Surveying and Mapping Technology Co., Ltd., Shenyang, Liaoning, China

ABSTRACT: This paper introduce the methods and common characteristics in deformation monitoring of mine slope and the need to establish CORS (Continuous Operational Reference System), which based on the significance of deformation monitoring of mine slope. It validates the feasibility of application in deformation monitoring of mine slope combined with the actual situation of mine slope.

1 THE SIGNIFICANCE OF DEFORMATION MONITORING OF MINE SLOPE

Nowadays, with the rapid development of China's economy, the demand for energy and mineral resources is also a substantial increase. In order to increase yields, all districts make great efforts to expand the scale of production, but the ensuing increase in production at the same time that these project area and operation of the project during the formation of slope safety (deformation) monitoring issues.

In slope engineering construction, through safety monitoring the slope engineering, this can play a role in some of the following:

- We should evaluate the stability during slope construction and use, make such deformation forecasting. For sliding and slid landslide, we should control their evolution, in time to capture the characteristics of collapse and hazard information, such as the correct analysis and evaluation, forecasting and management of slide, landslide and related projects, providing reliable information and scientific evidence.
- To prevent landslides and possible slip and creep, we should provide timely decision support, the boundary conditions of prediction and forecasting landslide, scale, sliding direction, time of occurrence and degree of harm, and to take timely measures to avoid and mitigate disaster losses.
- By monitoring, we can provide the corresponding parameter basis of the parties to departments for decision-making, provide relevant information to develop disaster prevention and relief corresponding countermeasures.
- For the monitoring slid failure and reinforcement landslide, the monitoring results are the scale to evaluate the treatment effect.
- To provide parameters, for carrying out the numerical simulation of displacement back analysis.

2 THE COMMON METHODS AND CHARACTERISTICS OF DEFORMATION MONITORING OF MINE SLOPE

There are three current commonly used methods in mine slope deformation monitoring, namely geodetic method, close-range photogrammetric method and GPS method. Now we compare the characteristics and applicability of these methods, as show in table 1:

3 THE NECESSITY AND SIGNIFICANCE OF CORS ESTABLISHED

- The establishment of the CORS can greatly improve the survey accuracy, speed and efficiency, reduce labor intensity and cost.
- The establishment of the CORS can real, effective, long-term monitor the deformation of construction, fast prediction of disaster.
- CORS will be an important part of the digital mine, and establish the mine's 3d, dynamic, geocentric reference frame, and thus achieve a real digital mine from the real surface of the spatial location information.

Table 1. Compare current commonly used methods.

Common monitoring methods	Monitoring instrument	Characteristics of the method	Applicability of the method
geodetic method	Total Station	Precision, high speed, high degree of automation, easy to operate, saving manpower, track automatically continuous observation and large amount of monitoring information	Adapt to different stages of deformation displacement monitoring; as the limits conditions of the terrain, adapt to larger rate of the horizontal deformation displacement and crag change of landslide cracks monitoring; influenced by climatic conditions
close-range photogrammetric method	Measurement Camera	large amount of monitoring information, saving manpower, putting fast, safe, but relatively low accuracy	adapt to larger rate of the horizontal deformation displacement and crag change of landslide cracks monitoring; influenced by climatic conditions
GPS method	GPS receiver	Precision, putting fast, easy to operate, all-weather observation, terrain and sight unrestricted; high cost but developing promising	adapt to three-dimensional displacement monitoring of Slope body' surface in different deformation stage

4 SINGLE BASED STATION CORS SYSTEM

4.1 *The principle of single based station CORS system*

Single base station CORS is only a continuously operating reference stations. Like RTK of one plus one or one plus N, but the base station consists is instead of a continuously operating reference station. A control software of base station real-time monitor satellite state, store and transmit data, while a server provide differentiated services network and user management.

The principle of the system is as follows:

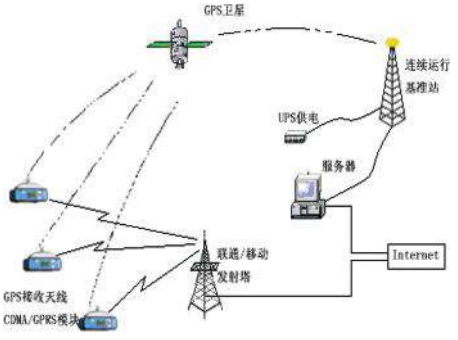

Figure 1. The diagram of the entire system.

4.2 *The advantages of single based station CORS system*

- Less investment;
- You can upgrade and expansion at any time;
- Data reliability, stability, security;
- Wide range of operations;
- Short construction period.

5 FEASIBILITY OF THE APPLICATION EXPERIMENT

5.1 *Monitoring network of slope plane displacement*

Case in a surface mine to study in Anshan. Monitoring points are based on characteristics of the slope to choose. On-site field surveys, we conduct the safety monitoring network optimization, network conduction and initial observation. Considered in the design optimization, we enhanced grid structure, taking into account the situation and development trend of conventional high-precision measuring instruments. There are seven monitoring points, numbered form 01~07, alone the slope of the distribution. The ultimately determine design shown in Figure 2.

5.2 *Comparison and analysis of parameter selection*

5.2.1 *Comparison height cut-off angle*

There are three high cut-off angles of 15°, 20°, 25°, using HDS2003software to solute baselines,

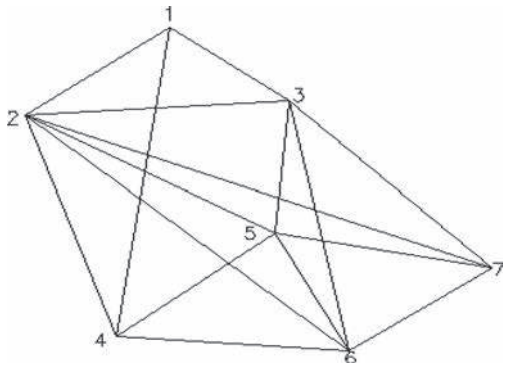

Figure 2. The design figure of monitoring network.

through comparison of the GPS network observations with conventional corner, the choice of cut-off angle 20 ° height works best.

5.2.2 *Comparison session length*

It broken down into 3 hours, 6 hours, 12 hours for observation data of twelve hours and high cut-off angles of 20°.Using HDS2003 software to solute, through the influence of the baseline analysis shows that: 3 hours observation can meet the requirements, six hours and twelve hours of observations were no significant differences observed values.

5.2.3 *The starting point coordinates precision*

The reference point 01 as starting point, using HDS2003 for a sophisticated baseline solver. Through comparison with the results of joint measurement geocentric coordinates and concluded: starting point joint measurement precision geocentric coordinates can be improve the accuracy of baseline solution, its impact on the results of baseline solution that can not be ignored.

5.3 *Four parameters for solving*

We check out the location in the mining area based on the control network results table of the original mine, according to the actual distribution of the control points, select the measurement sequence and walking routes, determine the points for solving four parameters and checking. Obtain the four parameters by using the three of points:

szdCx1 = 153.4178875911,
szdCy1 = –284.0327895976,
szdCa1 = 0.00003869900054746,
szdCk1 = 0.99997218215827788,

The other point to check, ΔX = 0.021 m, ΔY = 0.008 m, ΔH = 0.002 m, Check is successful.

Table 2. Accuracy of calculation in different cut-off elevation angles.

High cut-off angles	RMS MIN (mm)	RMS MAX (mm)	RMS MEAN (mm)	Ratio MIN	Ratio MAX	Ratio MEAN
15°	4	6	5.07	7.3	16.6	5.15
20°	4	5	4.85	6.6	16.7	5.43
25°	4	5	4.78	4.9	16.9	5.51

Table 3. Accuracy of calculation in different session lengths.

High cut-off angles	RMS MIN (mm)	RMS MAX (mm)	RMS MEAN (mm)	Ratio MIN	Ratio MAX	Ratio MEAN
3h	4	13	6.5	7.9	21.4	9.4
6h	3	10	7.3	8.9	64.7	22.4
12h	2	13	6.9	7.6	39.8	15.5

4	0.021	0.007	–0.003
5	–0.023	0.003	0.023
6	–0.011	–0.025	0.047
7	–0.025	–0.005	0.039

5.4 *Achievement test*

Measuring preserved relatively intact points one by one in the original control network in the mining area, real-time saving each measurement data, transmitting and processing the data after observation. Comparing the results with the results of original control network as follows:

6 CONCLUSION

The experiments in this paper is the use of single based station CORS system to measure the well-preserved known points in the network of the

mine, and to test accuracy, stability and reliability of the single based station CORS system. It proven single based station CORS system stability, simple operation, high precision, constantly monitor, expanding the range of operations, used for mine slope deformation monitoring can greatly save manpower, material and financial resources.

Study on building permanent underground refuge chamber in Dayangquan Coal Mine

Tian Zhang, Longzhe Jin, Na Gao & Xiao Huang
School of Civil and Environment Engineering University of Science and Technology Beijing, Beijing, China

ABSTRACT: By analyzing the conditions of Dayangquan Coal Mine, a permanent refuge chamber was constructed in an abandoned underground. By analyzing the risk factors, the protection functions of the permanent refuge chamber were determined to be heat-resistant, anti-explosion and gas-outburst-prevention. The space was divided into buffer area, emergency area and refuge area. The total length of the chamber was determined to be 33 m, the width to be 4.2 m and the effective area to be 138.6 m^2 according to the size of magazine, people and equipment. According to the per capita air supply volume, the minimum air supply volume of the compressed air supply system was 14.4 m^3/min for 40 persons. The minimum oxygen supply volume of oxygen generation purifier was 24 L/min. The fireproof anti-explosion airtight system was composed of 4 protection doors which was determined. The study provides reference for the building of permanent refuge chambers with similar scales.

1 INSTRUCTION

Coal mines in China are mostly underground mining with characteristics of complicated environment and varied accident types, etc. In recent years, the underground accidents occur frequently in the coal mines in China with mass casualties and property damages which restrict the development of coal industry in the country. According to relevant statistical data, the number of persons who died on the spot with the reasons of explosion and high temperature, etc. only accounts for about 10% of the total casualties. Most casualties are caused by oxygen depletion, asphyxiation from high concentration poisonous and harmful gases, blocking-up of escape route, etc. This paper carries out study on the site selection and building of permanent refuge chamber and the key techniques of various life support systems which have important significance not only to the improvement of emergency rescue capacity of Dayangquan Coal Mine but also to the building of permanent refuge chambers with similar size (Yang 2002).

2 THE GENERAL SITUATION OF DAYANGQUAN COAL MINE

2.1 *The situation of mine distribution*

Dayangquan Coal Mine is located to the south of Xiyuzhang Village, Yijing Town, Yangquan City, with the length of 3.7 km from west to east, and the width of 4.0 km from south to north. Currently, mining is mainly conducted at No. 12 and 15 coal seams. The mine field covers an area of 10.7891 km^2, with a mining elevation of 650–450 m. The stratum of mine is northeast to southwest tilt, with a dip angle of about 10°, and a fault throw of about 20 m. Fully-mechanized excavating and blasting methods are adopted for the mine. The driving face is divided into haulage roadway, rail roadway and return airway, and the stope face is divided into haulage tunnel, return air tunnel and tail roadway. The length of stope face of No. 12 coal seam is 180–200 m, and that of No. 15 coal seam is 150–180 m. The main support patterns are anchor rod anchor cable and anchor mesh.

2.2 *Underground mining conditions*

The conditions underground:

1. Gas conditions: based on an appraisal, the absolute gas emission rate of Dayangquan Coal Mine is 89.5 m^3/min, and the relative gas emission rate is 37.61 m^3/t, so it is a highly gassy mine.
2. Coal dust conditions: the minimum ignition temperature of coal dust cloud for No. 12 coal seam is 900°C, and that of No. 15 coal seam is 920°C. The coal dust in both seams is non-explosive.
3. Water content: the normal water inflow of No. 12 coal seam and No. 15 coal seam is about 45 m^3/h, and 80 m^3/h in maximum. There are mainly water seepage from the roof, the shaft and the goaf, among which the seepage from goaf is the major source of the mine inflow.

4. Geothermal and geostatic pressure: according to coalmine production practices, there have been no abnormal phenomena of geothermal and geostatic pressure found till now.

According to the general situation of Dayangquan Coal Mine, the permanent refuge chamber will be constructed in No. 12 coal seam or No. 15 coal seam, which can resist damages caused by accidents of highly gassy mine, such as fire, explosion and outburst of gas.

3 STUDY ON SITE SELECTION OF THE PERMANENT REFUGE CHAMBER

3.1 *Principles of site selection*

Chamber siting rules:

1. The refuge chamber shall not be arranged at places with potential safety hazards, such as substations, explosive magazines and oil storage facilities (Sun 2010).
2. The refuge chamber shall be constructed in areas with stable surrounding rocks and shall be far away from places such as faults, which are liable to be affected by mining and geological activities (Mickey 2007).
3. Underground hydrogeology and mining area distribution shall be considered for site selection of the refuge chamber, and it is required to be arranged on the mining route for avoiding of disasters (Rick & Graham 1999).
4. The refuge chamber shall be constructed by taking full use of existing chambers which are well supported, so as to reduce the construction cost and construction period (Yu et al. 2010).

3.2 *Determination of site selection*

Mining was mainly conducted in No. 12 coal seam and No. 15 coal seam of Dayangquan Coal Mine. Specifically, it was conducted on working face 2121 of No. 12 coal seam, and working face 8125 of No. 15 coal seam. Based on the distribution of underground mining area, hydrogeology and situations of the existing chambers, the permanent refuge chamber of Dayangquan Coal Mine was finally selected in the abandoned explosive magazine at +630 mining level in No. 12 coal seam (as shown in Fig. 1).

The advantages of the site:

1. The chamber was existing, with a clear height of 2 m, so the dimensions of chamber was close to the requirement of building size so as to reduce the construction period and construction cost.
2. This site was about 600–700 m away from the personnel on working face of No.12 coal seam, thus the specified requirements that the distance from refuge facilities should not exceed 1000 m can be satisfied.
3. The surrounding areas exceed 1000 m were provided with moveable refuge chamber as the refuge space. Its length was enough for 30 mobile personnel in the roadway to avoid dangers.

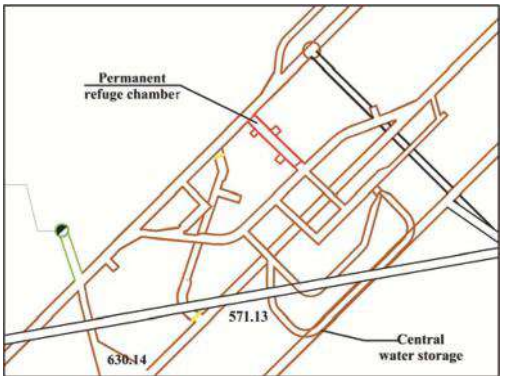

Figure 1. The site of the permanent refuge chamber at +630 mining level in No. 12 coal seam for 40 persons.

4 STUDY ON FUNCTIONAL STRUCTURE AND SCALE OF THE PERMANENT REFUGE CHAMBER

4.1 *Study on basic function and structure of refuge chamber*

4.1.1 *Function of refuge chamber*

Based on the risk factors of Dayangquan Coal Mine, the permanent refuge chamber of No. 12 coal seam has the functions such as high temperature resistance, shock resistance and air-tightness. The protection parameters are shown in Table 1 (Sui 2007).

4.1.2 *Structure of refuge chamber*

Based on relevant specifications and major functions of the chamber, the space of the permanent refuge chamber of Dayangquan Coal Mine was divided into the three areas (as shown in Fig. 2).

1. Buffer area: it prevented the poisonous gas from entering the chamber along with the refuge personnel. There were air curtain isolation system, sanitary fittings and power control system arranged within this area.
2. Refuge area: as the major movement area of refuge personnel, it provided the refuge personnel with oxygen supply system, refrigerating system, purification system, monitoring and controlling system, communication system, food and water, which were necessary for survival.

Table 1. The protection parameters of the permanent refuge chamber of Dayangquan Coal Mine.

Protective performance	Protective parameters
Resistance to instantaneous high temperature	>1000°C
Resistance to explosion shock	>0.5 MPa
Airtight function	CH_4, CO
Oxygen volume	18%~23%
Interior temperature	35°C
Interior humidity	80%
Monitoring	CO, O_2, CH_4, CO_2
Communication and signal transmission	Not less than two methods

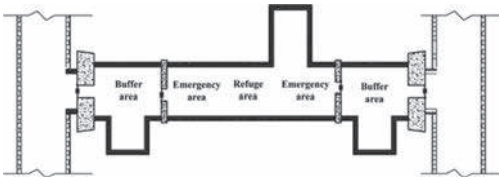

Figure 2. The area distribution of the permanent refuge chamber of Dayangquan Coal Mine.

3. Emergency area: it provided the injured refuge personnel with simple curing. There were simple medical supplies, equipment and stretchers arranged within this area.

4.2 *Building size of the refuge chamber*

4.2.1 *Overall dimensions of the refuge chamber*

The overall dimensions of the permanent refuge chamber of Dayangquan Coal Mine were determined by total receiving capacity, equipment volume, safety factors of spatial size.

1. Effective area of chamber

$$S = (S_1 \times \mathrm{n} + S_2 + S_3) \times R \times K \quad (1)$$

where S = effective area of the chamber; S_1 = the average effective area; n = the rated receiving capacity of the chamber; S_2 = the equipment area of the refuge chamber; S_3 = the area of protecting wall; K = the safety dimension factors of the chamber; and R = impact factor of the spatial environment. The calculated effective area of chamber was 138.6 m^2.

2 Overall dimensions of chamber

① Length:

$$L = A + 2 \times B + 2 \times (C + D) + E \quad (2)$$

where L = the overall length of the chamber; A = the length of the refuge area; B = the length of buffer area; C = the thickness of internal protecting wall; D = the thickness of external protecting wall; and E = the length of the shoring roadway of the chamber. The calculated total length of refuge chamber was 33 m.

② Width:

$$W = \frac{S}{L} \quad (3)$$

where W = the width of chamber; S = the effective area of chamber; and L = the total length of chamber. The calculated effective width of chamber was 4.2 m.

③ Height:

Based on the requirements for equipment, personnel and spatial size, the effective height of main chamber was determined as 3.4 m, and that of the auxiliary chamber was 2.8 m.

Finally, the total length of the permanent refuge chamber of Dayangquan Coal Mine was 33 m, the length of buffer area of the chamber was 6 m, and that of the refuge area was 15 m. The two auxiliary chambers were 3 m in depth (the intermediate chamber was originally owned by the explosive magazine), and main chamber section was 3.4 m in effective height and 4.2 m in effective width; the auxiliary chamber was 2.8 m in effective height and 3.0 m in effective width(as shown in Fig. 3).

4.2.2 *Study on sectional dimensions and supports of the refuge chamber*

According to the theory of loose circle, the permanent refuge chamber of Dayangquan Coal Mine belongs to big broken rock zone, class IV, thus the combination of anchoring, meshing and shotcreting was applied for supporting.

1. Sectional dimensions: according to the theory of loose circle, the sectional dimensions for semicircular arch structure were as follows: the clear width of main chamber was 4.2 m, the diameter of semicircular arch was 2.1 m, and the height of chamber wall (including chamber floor) was 1.6 m; the clear width of auxiliary chamber was 3.0 m, the diameter of semicircular arch was 1.5 m, and the clear height of chamber wall was 1.3 m.
2. Support type: secondary support method was adopted according to the type of wall rock and the experience: the primary support applies anchor, anchor cable, anchor net and shotcreting method, with the specifications of anchor cable being ① $\Phi 21.6 \times 8300$ mm, ② $\Phi 21.6 \times 6300$ mm and the anchoring length being 1000 mm. The secondary arch building support, with the strength being C30, was provided with joist steel of No. 11 and metal mesh(as shown in Fig. 4).

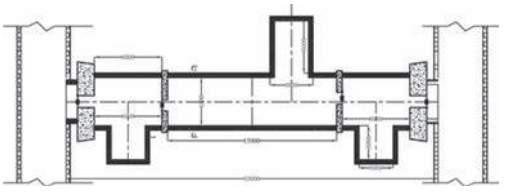

Figure 3. The overall dimensions of the permanent refuge chamber of Dayangquan Coal Mine.

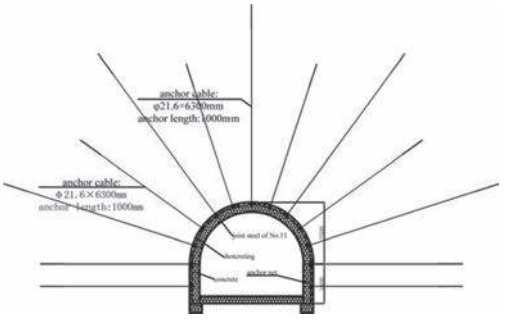

Figure 4. The cross dimensions and supporting pattern of the permanent refuge chamber of Dayangquan Coal Mine.

5 STUDY ON LIFE SUPPORT SYSTEMS OF THE PERMANENT REFUGE CHAMBER

In order to meet living needs of refugees, the refuge chamber of Dayangquan Coal Mine was provided with fireproof anti-explosion system, air curtain isolation system, oxygen supply system, communication system, safety monitoring and control system, refrigeration and dehumidification system and auxiliary system. As the oxygen supply system and fireproof anti-explosion airtight system were used as crucial protection system against fire, high temperature, explosion and gas outburst, they would be studied with emphasis.

5.1 *Study on oxygen supply system*

According to the ground conditions of the permanent refuge chamber of Dayangquan Coal Mine, drilling was inadvisable. Therefore, the mode of "two-stage oxygen supply" was adopted so as to meet oxygen demands of refugees, including mine compressed air oxygen supply system and oxygen generation purifier (Gao et al. 2012).

5.1.1 *Compressed air oxygen supply system*

For the mine compressed air oxygen supply system, fresh air is transferred into the refuge chamber by the ground compressor and compressed air duct, and then released into the space uniformly after depressurization, flow stabilization and noise reduction by the compressed air control system of the refuge chamber. According to the differential pressure principle, contaminated air is vented through return air duct to realize air circulation.

As average air supply per capita shall not be less than 0.3 m^3/min, the total air supply of the refuge chamber should be determined as:

$$Q = Q_1 \times n \times K \tag{4}$$

where Q = total air supply of refuge chamber per unit time; Q_1 = average air supply per capita; n = the capacity of refuge chamber; and K = safety factor. The minimum calculated air supply should be 14.4 m^3/min.

5.1.2 *Oxygen generation purifier*

When external air supply pipes of underground compressed air supply system were damaged or forcing fan was broken down, the oxygen generation purifier must be started. The system was composed of three parts, i.e. conflux system, control system and purification system.

1. Conflux system: oxygen from oxygen bottles was organized uniformly and then conveyed to the control system through pipeline.
2. Control system: input oxygen went through the processes of depressurization, current stabilization and noise reduction. According to actual person number in the refuge chamber, a certain amount of oxygen was sent to the purification system.
3. Purification system: co_2 generated by human body was absorbed and purified and then released into air together with input oxygen so as to meet air supply demands.

Total oxygen storage volume of the oxygen generation purifier system in the permanent refuge chamber of Dayangquan Coal Mine was:

$$Q_y = q \times n \times K \tag{5}$$

where Q_y = total volume of the oxygen generation purifier system; q = average air demand per capita, rated; n = the capacity of refuge chamber; and K = safety factor. The minimum calculated oxygen storage volume of the oxygen generation purifier system of Dayangquan Coal Mine was 24 L/min.

5.2 *Study on fireproof anti-explosion airtight system*

The fireproof anti-explosion airtight system of the refuge chamber was used to protect the chamber

against damages from fire, explosion and gas outburst accidents, which was the first course of protection system of the chamber. The system includes: fireproof anti-explosion airtight door and fireproof anti-explosion airtight wall.

1. Fireproof anti-explosion airtight door

As indicated in the figure 3, the permanent refuge chamber of Dayangquan Coal Mine was provided with 4 fireproof anti-explosion airtight doors on both sides. Two outside protective doors were mainly used to realize anti-explosion, high temperature resistance and airtight functions. The door body should be made of 16Mn steel with yield strength and elasticity modulus respectively as 350 MPa and 206GPa. Two medium protective doors were mainly used to realize airtight function with total weight less than that of outside protective door.

2. Fireproof anti-explosion airtight wall

Fireproof anti-explosion airtight walls of the chamber were similar to the protective doors, with main functions of anti-explosion, high temperature resistance and airtight. In order to guarantee overall performance of the doors and walls, they should be grouted as a whole with concrete of C30.

The system was enough strong to resist instantaneous high temperature of 1000°C, continuous high temperature of 260°C and shock wave greater than 0.5 MPa. Meanwhile, anti-explosion airtight doors were flexible, swift and airtight in manual startup mode (Silvestrini et al. 2008).

5.3 *Study on other systems*

Other systems were set in the refuge chamber for the basic survival needs.

1. Air curtain isolation system

The air curtain isolation system was mounted above the entrance of external protective door of the permanent refuge chamber of Dayangquan Coal Mine. When refugees enter, an air curtain was formed by this system, and it could effectively prevent toxic gas from entering into the refuge chamber with refugees.

2. Safety monitoring and control system

The safety monitoring and control system which was mounted on the inside and outside of the refuge chamber of Dayangquan Coal Mine can monitor temperature, humidity and the changes of CO, CO_2, O_2, CH_4, H_2S and then transfer the data to ground control center so as to facilitate dispatching (Zhang 2005).

3. Refrigeration and dehumidification system

All the persons and equipment would release water and heat during refuge and operation to cause temperature and humidity rise, which would finally bring about suppression in the chest and heatstroke to refugees. In case of serious situation, it would treat to life. Ice generation refrigeration and dehumidification system was adopted in the refuge chamber to maintain indoor temperature not greater than 35°C and humidity not greater than 80% (Luo et al. 2005, Xu & Li 2005).

4. Auxiliary systems

The auxiliary systems of the permanent refuge chamber could meet basic survival needs of refugees, including lighting system, power system, water, food, sanitary installation, armamentarium, fire fighter and self-rescuer.

6 CONCLUSIONS

The following conclusions can be drawn according to the study.

1. Based on the analysis of the mine conditions, it was determined that the permanent refuge chamber would be located in the abandoned plane explosive magazine at +630 mining level of No. 12 coal seam; this option reduced construction period and cost.
2. Based on the analysis of main harmful factors of the mine, it was determined that main functions of the permanent chamber were resistance to high temperature and shock and air-tightness.
3. According to function demands of the refuge chamber, the space was separated into buffer area, emergency area and refuge area.
4. According to per capita area, equipment volume and space dimensions, it was determined that effective area of the refuge chamber was 138.6 m^2 with an overall length of 33 m; for the main refuge chamber, the section should be in arch shape with an effective height of 3.4 m and an effective width of 4.2 m; for auxiliary chambers on both sides, the dimensions were a depth of 3 m, an effective height of 2.8 m and an effective width of 3.0 m. They should be supported in combined methods of grouting, anchorage and arching.
5. According to air supply volume per capita, it was determined that the minimum air supply volume of compressed air oxygen supply system was 14.4 m^3/min and that of oxygen generation purifier was 24 L/min.
6. According to requirements for anti-explosion, high temperature resistance and airtight performance, the fireproof anti-explosion airtight system should be composed of fireproof anti-explosion airtight doors and walls. The doors should be made of 16 Mn steel and the walls should be constructed by C30 concrete.

Study on distribution law of lead abutment pressure in fully mechanized caving face with large mining height

Fu-Lian He, Zhi-Yang Liu, Tong-Da Li, Sheng-Rong Xie, Huan-Kai Wu & Zhen Wei
School of Resource and Safety Engineering, China University of Mining and Technology (Beijing), Beijing, China

ABSTRACT: As the lead abutment pressure in fully mechanized caving face is difficult to be described quantitatively, the front coal mechanical model of mechanized caving face is established. The calculation formula of abutment pressure value and its distribution width is obtained by using elastic-plastic limit equilibrium theory. Furthermore, this paper researches the main factors of limit equilibrium area width and conducts formula derivation of horizontal displacement of the coal in limit equilibrium area. Results shows that: firstly, the lead abutment pressure increases with the increasing distance to working face in mechanized caving face, and arrives at the peak value in elastic-plastic junction. Secondly, the limit equilibrium width increases with the increasing mining height, roof coal thickness, occurrence depth, literal pressure coefficient and attenuation coefficient, and decreases with increasing caving ratio, coal-rock cohesion and internal friction angle; thirdly, the horizontal displacement in plastic area has linear increasing relationship with the plastic area width, Poisson's ratio of coal, and has inverse proportion with elastic modulus of coal. Lastly, the practical example of 8313 fully mechanized caving face of Dongrisheng coal mine of Pingshuo mining area verifies the rationality of mechanical model and calculation formula.

Keywords: lead abutment pressure, fully mechanized face, elastic-plastic limit equilibrium theory, horizontal displacement

1 INTRODUCTION

The lead abutment pressure caused by coal mining is one of essential reasons for dynamic disasters such as rock burst, water inrush and coal and gas outburst. Further research on distribution law of lead abutment pressure has significance of realizing the stability analysis of roadways, determination of fore-support distance and prevention of dynamic disasters (Pu & Liao 2002, Si et al. 2007). Domestic and abroad scholars have been researching the formation mechanism and distribution law of regular mining abutment pressure and thus put forward some mature theory and control techniques. However, in the condition of fully mechanized caving with large mining height, the research is conducted little. Because of stope structure, mining draft, mining height and roof coal, the distribution law of abutment pressure in fully mechanized caving face of thick coal seam performs specially (Liu et al. 2011, Yang et al. 2009, Gao et al. 2010). While, the present abutment pressure research methods focus on sites measurement and physical simulation, which only roughly judges abutment pressure distribution law. From the perspective of mechanical explanation, the research is not mature, and hence the lead abutment pressure is difficult to be described (Xie & Wang 2010, Xia et al. 2011, Jiang & Ma 2002). Therefore, the distribution law feature of fully mechanized caving face needs to be studied with mechanical way.

This paper takes the front coal of fully mechanized caving face with large mining height as research object. With the premise of adequate consideration to geological and production conditions, the lead abutment pressure of fully mechanized caving face is researched by means of elastic-plastic limit equilibrium theory, meanwhile, the nonlinear plastic modulus is introduced to deduct the horizontal displacement formula in plastic area, which provides basis for stope, roadway surrounding rock control and dynamic disasters prevention.

2 THEORETICAL ANALYSIS OF LEAD ABUTMENT PRESSURE IN FULLY MECHANIZED CAVING FACE WITH LARGE MINING HEIGHT

2.1 *Establishment of mechanical model*

Lead abutment pressure means the increasing vertical press of the front coal caused by mining, of which the value is usually 2~4 times than rock stress. In the role of high abutment pressure, the

front coal is easily damaged and enters limit equilibrium state. At the seam time, the abutment pressure transfers to the deep part of coal and even the elastic area. In the dynamic adjustment process of abutment pressure, the width of limit equilibrium area and its abutment pressure also dynamically changes (Zhao et al. 2011, Gong 2006). The coal body in limit equilibrium area is taken as the research object so as to conduct further study of the changing feature of lead abutment pressure. The mechanical model is established as shown in Figure 1.

According to the structure of fully mechanized caving stope and the mechanical characteristics, the assumptions are taken as follows: ① coal is uniform continuous medium and the elastic-plastic coupling influence of front coal is out of consideration in analysis process, and volumetric strain in front plastic area is zero; ② the relationship of horizontal and vertical stress is shown as follows:

$$\sigma_x = \alpha\sigma_y \tag{1}$$

Where, σ_x is horizontal stress, σ_y is vertical stress, α is lateral coefficient;

③ damage and deformation of plastic area meets Moore—Coulomb criterion:

$$\tau_{xy} = \sigma_y \tan\varphi_0 + c_0 \tag{2}$$

Where, τxy, c_0, φ_0 respectively are shear stress, cohesion and internal friction angle in interface.

④ taking the emergence and development defects in the roof deformation process into consideration, the roof coal is regarded as continuum damage body and thus the dynamic change occurs (Xie & Wang 2008, Wang 2011). In the elastic-plastic interface where $x = x_0$, stress boundary conditions are shown as follows:

$$\sigma_y|_{x=x0} = k\gamma H + \eta\gamma_0 M_0 \tag{3}$$

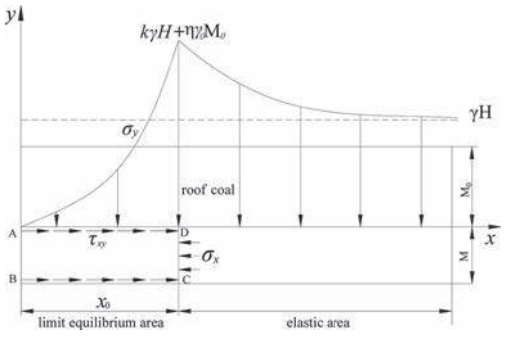

Figure 1. Mechanical model of limit equilibrium area coal.

Where, σ_y is vertical stress; K is stress concentration coefficient; γ is average bulk density of overlying strata; H is occurrence depth; η is attenuation coefficient; M_0 is roof thickness; γ_0 is roof bulk density; x_0 is width of limit equilibrium.

The advancing face direction is choose to x-axis, vertical direction is y-axis. And, the arbitraty unit coal in limit equilibrium area is taken as object, of which the height is M. The mechanical model is established as Figure 2. The unit is in limit equilibrium state and its equilibrium formula is:

$$Md\sigma_x - 2\tau_{xy}dx = 0 \tag{4}$$

2.2 *Deduction calculation of abutment pressure value and its peak position*

Combined with (1), (2) and (4), the followed formula is obtained:

$$\frac{d\sigma_y}{dx} - \frac{2\tan\varphi_0}{M\alpha}\sigma_y - \frac{2c_0}{M\alpha} = 0 \tag{5}$$

Differential Equation is solved as:

$$\sigma_y = \frac{M\alpha}{2\tan\varphi_0} e^{\frac{2\tan\varphi_0}{M\alpha}(x-c)} - \frac{c_0}{\tan\varphi_0} \tag{6}$$

Where, C is unknown constant, when the (6) is brought to (2), the followed formula is obtained:

$$\tau_{xy} = \frac{M\alpha}{2} e^{\frac{2\tan\varphi_0}{M\alpha}(x-c)} \tag{7}$$

Take the ABCD in Fig. 1 as research object, and the equilibrium formula is:

$$M\alpha\sigma_y|_{x=x_0} - 2\int_0^{x_0}\tau_{xy}dx = 0 \tag{8}$$

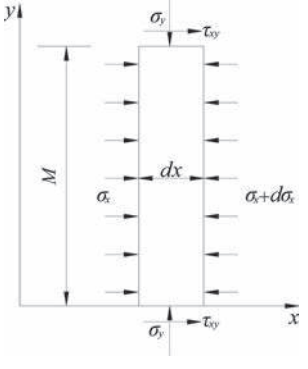

Figure 2. Mechanical model of unit body in limit equilibrium area.

When (8) is substituted by (6), (7), the followed formula is obtained:

$$C = \frac{M\alpha}{2\tan\varphi_0} \ln \frac{M\alpha}{2C_0} \tag{9}$$

When (9) is brought in (1), (6), (7), the following three formulas are obtained:

$$\sigma_y = \frac{c_0}{\tan\varphi_0} e^{\frac{2\tan\varphi_0}{M\alpha}x} - \frac{c_0}{\tan\varphi_0} \tag{10}$$

$$\tau_{xy} = c_0 e^{\frac{2\tan\varphi_0}{M\alpha}x} \tag{11}$$

$$\sigma_x = \frac{\alpha c_0}{\tan\varphi_0} e^{\frac{2\tan\varphi_0}{M\alpha}x} - \frac{\alpha c_0}{\tan\varphi_0} \tag{12}$$

When (10) is substituted by (3), the followed formula is obtained:

$$x_0 = \frac{M\alpha}{2\tan\varphi_0} \ln\left(\frac{k\gamma H + \eta\gamma_0 M_0 + c_0\cot\varphi_0}{c_0\cot\varphi_0}\right) \tag{13}$$

As is known from (10)~(12), σ_x, σ_y and τ_{xy} gradually increase in (0, x_0) and reach the maximum at x_0. According to (13), the width of limit equilibrium is affected by some factors such as mining depth, mechanical property of coal and rock, caving ratio. The following part conducts further study on influencing factors of lead abutment pressure distribution law.

3 INFLUENCING FACTORS ANALYSIS OF LIMIT EQUILIBRIUM AREA IN FULLY MECHANIZED CAVING FACE

3.1 *Occurrence depth*

When the parameters are set by: α = 0.3, c_0 = 0.5 MPa, φ_0 = 15°, k = 2, γ = 27 KN/m^3, γ_0 = 14 KN/m^3, M = 4 m, M_0 = 10 m, η = 0.9, the (13) is substituted as:

$$x_0 = 2.2\ln(1.2 + 0.03H) \tag{14}$$

As is known from the analysis of (14), H has logarithmic function relationship with x_0. When it is in (200, 600), the limit equilibrium width increases as the occurrence depth increases. Also, the expression formula of the width x_0 and H is obtained when the attenuation coefficient η = 0.2 and η = 0.6. The corresponding distribution curve of H—x_0 are shown in Fig. 3 when H is set by the following value 200, 300, 400, 500, 600.

As is known from Fig. 3, in the condition of other given parameters, the limit equilibrium width x_0 grows as H and η gradually increases.

3.2 *Caving ratio*

When the parameters are set by: α = 0.3, c_0 = 0.4 MPa, φ_0 = 20°, k = 2, γ = 27 KN/m^3, γ_0 = 14 KN/m^3, H = 300 m, η = 0.8, the coal seam thickness M_{total} = 14 m and the caving ration fcb: M/M_0, where M_0 = 14–M (3.5 < M < 7.5), then, (13) is substituted by:

$$x_0 = 0.42M\ln(1574 - 0.01M) \tag{15}$$

When $f(M) = M\ln(15.74 - 0.01M)$ (16)

If M is solved by first derivative and second derivative, the followed formula are obtained:

$$f'(M) = \ln(15.74 - 0.01M) - \frac{M}{1574 - M} \tag{17}$$

$$f''(M) = \frac{M - 3148}{(M - 1574)^2} \tag{18}$$

Apparently, f″(M) < 0, so f′(M) is monotonically decreasing function at (3.5, 7.5), and f′(7.5) > 0, and f(M) is monotonically increasing function at (3.5, 7.5), ie, f(M) increases with M increases. Therefore, the compound function related about M and x_0 is increasing function at (3.5, 7.5). Also, the expression formula of x_0 and M is obtained when the coal seam respectively are 12 m, 15 m and 18 m, and so is the corresponding f_{cb}—x_0 curve distribution figure.

As is known from the Fig. 4, if the other parameters are given, the width x_0 decreases with the caving ratio f_{cb} and coal seam thickness increase.

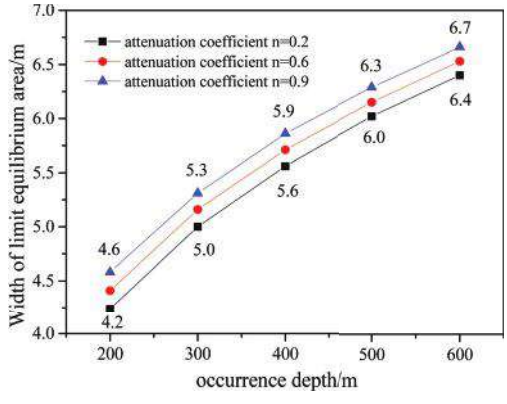

Figure 3. Relationship between limit equilibrium width and roadway occurrence depth.

3.3 *Thickness of roof coal seam*

When the parameters are set by: α = 0.3, c_0 = 0.5 MPa, φ_0 = 20°, k = 2, γ = 27 KN/m^3, γ_0 = 14 KN/m^3, H = 200 m, M = 5 m, η = 0.8 then, (13) is substituted as:

$$f(M_0) = 2.1\ln(8.8 + 0.1M_0) \tag{19}$$

As is known from (19), M_0 has logarithmic function relationship with x_0. The function monotonically increases (10, 40), ie, the limit equilibrium width x_0 grows with the roof coal thickness M_0 increases. The expression formula of x_0 and M_0 is obtained when the lateral coefficient α = 0.35 and α = 0.4. The corresponding distribution curve of M_0—x_0 are shown in Fig. 5 when M_0 is set by the following value 10, 20, 30, 40.

As is known from Fig.5, if the other parameters are given, the limit equilibrium width x_0 gradually increases with roof coal thickness and lateral coefficient.

3.4 *Mining height*

When the parameters are set by: α = 0.3, k = 2, γ = 27 KN/m^3, γ_0 = 14 KN/m^3, M_{total} = 15 m, H = 200 m, η = 0.9, if it is in the condition of less stable surrounding rock, c_0 = 0.5 MPa, φ_0 = 25°, and then (13) is substituted by:

$$x_0 = 0.32M\ln(10.9 + 0.1M_0) \tag{20}$$

Compared with regular fully mechanized caving face, the mining height is usually more than 3.5 m as to the fully mechanized caving face with large mining height. When (20) is substituted with the value of M that are 2 m, 2.5 m, 3 m, 3.5 m, 4 m and 4.5 m, the limit equilibrium width x_0 is obtained, and the variation law is analyzed. And, the corresponding distribution curve figure is drawn.

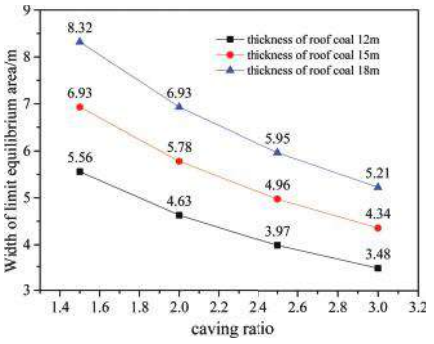

Figure 4. Relationship between limit equilibrium width and caving ratio.

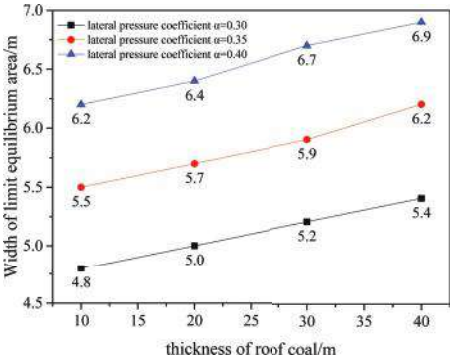

Figure 5. Relationship between limit equilibrium width and roof coal thickness.

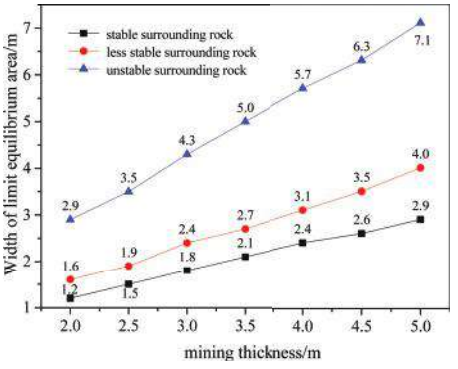

Figure 6. Relationship between limit equilibrium width and caving ratio.

As is known from the Fig. 4, if the other parameters are given, the width x_0 decreases with the caving ratio fcb and coal seam thickness increase.

4 HORIZONTAL DISPLACEMENT DEDUCTION OF PLASTIC AREA COAL IN FULLY MECHANIZED CAVING FACE

The transverse deformation of coal body in fully mechanized caving face is obvious of which the value could be obtained by means of the relationship between average stress and strain multiply the nonlinear plastic modulus.

According to the relationship between average stress σ and average strain ε:

$$\begin{aligned} \sigma &= \frac{1}{3}(\sigma_x + \sigma_y + \sigma_z) \\ \varepsilon &= \frac{1}{3}(\varepsilon_x + \varepsilon_y + \varepsilon_z) \end{aligned} \tag{21}$$

Generalized Hooke's theorem shows:

$$\begin{cases} \varepsilon_x = \frac{1}{E}\left[\sigma_x - \mu\left(\sigma_y + \sigma_z\right)\right] \\ \varepsilon_y = \frac{1}{E}\left[\sigma_y - \mu\left(\sigma_x + \sigma_z\right)\right] \\ \varepsilon_z = \frac{1}{E}\left[\sigma_z - \mu\left(\sigma_x + \sigma_y\right)\right] \end{cases} \tag{22}$$

(21) is further dealt to:

$$\varepsilon = \frac{1-2\mu}{E}\sigma \tag{23}$$

And, $$\varepsilon_x - \varepsilon = \frac{1+\mu}{E}\left(\sigma_x - \sigma\right) \tag{24}$$

Then:

$$\begin{cases} \varepsilon_x = \frac{1+\mu}{E}\left(\sigma_x - \sigma\right) + \varepsilon \\ \varepsilon_y = \frac{1+\mu}{E}\left(\sigma_y - \sigma\right) + \varepsilon \\ \varepsilon_z = \frac{1+\mu}{E}\left(\sigma_z - \sigma\right) + \varepsilon \end{cases} \tag{25}$$

The stress-strain relationship of the front coal body of plastic area and fully mechanized caving face with large mining height could be expressed with the above formula multiplied by plastic modulus Ψ. If the coal body was in elastic state, Ψ = 1. In the formula, E_0 is integrated elastic modulus of coal body in plastic area, and passion's ratio is μ_0. According to the basic assumption (1), ε = 0. According to the plain strain principle: $\varepsilon_z = 0$, $S_z = 0$, $\sigma_z = \sigma$. Combined with the above analysis:

$$\sigma = \frac{1}{2}(\sigma_x + \sigma_y) \tag{26}$$

$$\begin{cases} \varepsilon_x = \frac{\psi(1+\mu_0)}{2E_0}(\sigma_x - \sigma_y) \\ \varepsilon_y = \frac{\psi(1+\mu_0)}{2E_0}(\sigma_y - \sigma_x) \end{cases} \tag{27}$$

As to front coal body in large mining height face, it is extruded in the gob direction in the process of forming plastic area which makes coal body swell. In the situation that is out of swell deformation, the swelled coal area in gob side is equal to the reduced coal area in plastic region. Take the arbitrary point in plastic area as object, and the distance to coal wall is denoted by x. The horizontal displacement is denoted by S_x, and vertical displacement is S_y, then:

$$Mx = (x + S_x)(M - S_y) \tag{28}$$

Then the following formula is solved:

$$S_y = \frac{S_x M}{x + S_x} \tag{29}$$

And $\varepsilon_y = \frac{S_y}{M - S_y} = \frac{S_x}{x}$, this formula is derived by:

$$\frac{d\varepsilon_y}{dx} = -\frac{2\varepsilon_y}{x} \tag{30}$$

The differential equation is solved:

$$\varepsilon_y = \frac{B}{x^2} \tag{31}$$

Where B is constant, substitute (31) to (27):

$$\psi = \frac{2E_0 B}{(1+\mu_0)(\sigma_y - \sigma_x)x^2} \tag{32}$$

Appended with boundary conditions: $x = x_0$; $\Psi = 1$; $\sigma_y - \sigma_x|x = x_0 = (1 - \alpha)k\gamma H + \eta\gamma_0 M_0$:

$$B = \frac{(1+\mu_0)\left[(1-\alpha)k\gamma H + \eta\gamma_0 M_0\right]x_0^2}{2E_0} \tag{33}$$

Ψ is reverse solved when (32) is substituted (33):

$$\psi = \frac{\left[k\gamma H(1-\alpha) + \eta\gamma_0 M_0\right]x_0^2}{(\sigma_y - \sigma_x)x^2} \tag{34}$$

And

$$S_x = x\varepsilon_y \tag{35}$$

The horizontal displacement is obtained when (28) is substituted by (20), (27), $x = x_0$:

$$S_{x_0} = \frac{(1+\mu_0)\left[(1-\alpha)k\gamma H + \eta\gamma_0 M_0\right]x_0}{2E_0} \tag{36}$$

The results concluded from horizontal displacement analysis of (36) in plastic area are: ① horizontal displacement $S\ x_0$ is proportional with limit equilibrium width x_0, and increases with the increasing width; ② horizontal displacement S_{x_0} is reversely proportional with integrated elastic modulus E_0 and has linear increment relationship with passion's ratio of plastic area coal.

5 ENGINEERING APPLICATIONS

The average coal occurrence of 8313 working face of Dongrisheng coal mine of Pingshuo mining area

is 191 m. Coal inclination is 1~3° which belongs to nearly horizontal coal seam. The thickness of coal seam is 12.81~16.95 m of which the average value is 15.11 m. The mining coal seam belongs to thick coal seam and its roof and floor rock strata belong to sandy mudstone and siltstone and have stable structure. The working face is with a large mining height that is M = 4.1 m, the caving height is 11.01 m and the ratio is 1:2.69. Based on the above theory, the abutment pressure is analyzed. The related parameters are:$\alpha = 0.25$, $c_0 = 0.3$ MPa, $\varphi_0 = 15.8°$, $k = 2$, $\gamma = 27$ KN/m^3, $\eta = 0.8$, $\gamma_0 = 14$ KN/m^3, $P_0 = 200$ KPa, $\mu_0 = 0.306$, $E_0 = 3.2$ GPa. When they are substituted in (12):

$$x_0 = \frac{M\alpha}{2\tan\varphi_0}\ln\left\{\frac{k\gamma H + \eta\gamma_0 M_0 + c_0\cot\varphi_0}{c_0\cot\varphi_0 + P_0/\alpha}\right\} = 3.38 \text{ m}$$

$$S_x = \frac{(1+\mu_0)\left[(1-\alpha)k\gamma G + \eta\gamma_0 M_0\right]x_0}{2E_0} = 188 \text{ m}$$

Because of mining, abutment pressure transfers to deep part. Combined with relative study (Xie et al. 2006), disturbance coefficient $\beta = 1.82$, so the limit equilibrium width of front coal in 8313 face $x = \beta x_0 = 6.15$ m.

The average displacement value measured in field is 210 mm when the limit equilibrium width is 6.57 m.

6 CONCLUSIONS

1. Lead abutment pressure increases with the distance to face increases and reaches the maximum in the interface of elastic and plastic, besides, the value and maximum position of abutment pressure are affected by some factors such as mining depth, mechanical property of coal and rock, and caving ratio;
2. The limit equilibrium width increases with the increasing mining height, roof coal thickness, occurrence depth, literal pressure coefficient andattenuation coefficient, and decreases with increasing caving ratio, coal-rock cohesion and internal friction angle;
3. As is known from transverse displacement of coal body in plastic area, the horizontal displacement in plastic area has linear increasing relationship with the plastic area width, Poisson's ratio of coal, and has inverse proportion with elastic modulus of coal;
4. The practical example of 8313 fully mechanized caving face of Dongrisheng coal mine of Pingshuo mining area verifies the rationality of mechanical model and calculation formula which has more extensive applicability.

The explosion-proof design of Abandoned Mine Detection Robot

Liwei Lei, Bin Zhu & Ruiqing Jia
School of Mechanical Electronic and Information Engineering of China University of Mining and Technology (Beijing), Beijing, China

ABSTRACT: How to exploit and utilize abolished mine has become a new issue of recycling resources in the world today. The explosion-proof design for coal robots which is used to detect the environment must be adopted. Based on a study of the necessity of the abandoned mine reuse, the wheel mine detection robot which designs for detecting the environment of abandoned mine is introduced. This paper is focus that the explosion-proof designs of the mine detection robots. The reference for the mine detection robots design will be provided in the future.

1 INTRODUCTION

Along with mining activities, abandoned mine is naturally produced as abandoned land. According to the characteristics of different abandoned mine, how to reform and rebuild is a way of "recycling resource" in many mining powers. In the middle of the 20th century, the research of abandoned mine has been begun in the UK, Germany, the United States of America and other developed countries. Meanwhile, a series of solutions have been put forward (Miao & Qian 2009). Mineral resources are very rich in our country who is a mining giant. There are a large number of abandoned mines are formed by several of reasons every year. Based on *the "12th five-year" plan on coal mine safety production* announced by The national security agency, 9535 small coal mines were closed because of unsafe in the "11th five-year plan" period. There are 459 state-owned key coal mines have been abandoned and more than 1100 mine pits that had been or would be shut down in the list released by the SAWS (State Administration of work safety) in 2007. A lot of mine pits would be closed too because of other reasons. The abandoned mine pits will do great harm to the natural environment though it has been closed. Some produce a large number of harmful gas leak in the earth's surface, threatening the normal production and life of human beings (Garden 1983, Thielemann & Welte 2001, Tang et al. 2005). Some turn into the pollution source of groundwater, endangering the human condition (Hu & Yan 2000). Others caused the surface subsidence, damaging the people's life and property safety (He & Qiu 2000). To solve the above problems, some experts and scholars put forward the study of governance the abandoned mine. Some abandoned mines can turn into warehouse, garage, museums and other facilities to save precious land resources. Some can mine the mineral resources again. Others which are useless must carry on the corresponding processing to prevent damaging human being. The recycling of the abandoned mine is very necessary and beneficial, it is not only good for environmental protection but also promote comprehensive utilization of resource (Zheng & Zhao 2003, Meng 2011, Xie & Tang 2010).

In order to draft the treatment measures for the abandoned mines reasonably, the investigation to it inside is necessary. Due to the environment of abandoned mine is complex, the person in the mine pits may be damaged by the explosive gas and other accidents occurring at any time. Thus, the robot needs to be designed for replacing or partly replacing the person into the mine pits. And, the AMDR (Abandoned Mine Detection Robot) must be flexible, reliable and possess good obstacle-surmounting. The logical judgement ability is needed in a poor communications and unknown information environment. Obvious, the most important is still higher safety performance.

2 THE OVERALL FLAME-PROOF DESIGN OF AMDR

The environment of abandoned mine pits is worse than the ordinary ones. The flooded shafts and collapses and other accidents may happen at any time because of the lack of ventilation measures, high temperature, harmful gases, dust, severe hypoxia condition and the underground situation is more complex and changeable.hence, the AMDR safety performance must be much higher than all the other equipments in the mine. Thus, it is necessary

to conduct a comprehensive control of the AMDR safety as a whole.

2.1 *The strategy of flame-proof structure adopted*

The AMDR is equipped with some instruments that are used to detect the surrounding environment and transfer information back to the control centre. The explosion risk is very high when these instruments and equipments in service. So, we should use the intrinsically safe electrical equipment or other special design for the electrical equipment. In principle, the flame-proof equipment is not allowed to use in mine. But the intrinsically safe electrical equipment is very rarely at present, especially the power supply, motor and other key equipments. Therefore, the AMDR adopted the safety strategy of flame-proof after the redundant safety measures drawn up in the case of the basic principles of electric explosion-proof allowed.

2.2 *High performance materials selected*

There is a possibility of explosion because of underground gas and dust accumulation. Static electricity and sparks can't be caused during the AMDR working time. The friction, spark resistance and antistatic properties of the material which used underground are made clear rules by the nation. The AMDR subjected to friction, collision inevitably as working. For this reason, the materials with special properties will be used to avoid explosion by reducing the static electricity and sparks in the working process.

2.3 *Safety communication methods selected*

There is no strict unified limitation about the EM (electromagnetic) equipment working underground. The SAWS made some limits for the use of EM equipment under mine. According to the IEC 60079-0-2007 *Explosive atmospheres–Part 0; Equipment-General requirements,* the transmitted power of EM waves is less than 6 W and the frequency of EM wave was made a certain limitation.

3 THE FLAME-PROOF ENCLOSER DESIGN OF THE AMDR

Flame-proof encloser is a platform to contact walking mechanism and also a shell to protect the internal electrical components. The AMDR should be strong enough to withstand the internal or external explosion of combustible gas. And it must have enough space to accommodate control system, power system, communication system, detection instrument. The interface which contacts flame-proof encloser and walking mechanism is the key part of power output. It must meet the requirements of flame-proof. Finally, flame-proof encloser must be good at heat dissipation to prevent temperature rising that can causing an explosion. To sum up; flame-proof encloser has the very high request in material selection and structure design.

3.1 *The explosion-proof encloser material selected of the AMDR*

The national standards for the coal mine equipment shell material are clear. But the material is not ruled strictly for the mine robot flame-proof enclosure. The cast steel, ordinary mine equipment shell material, couldn't meet the requirements of the AMDR obviously with high precision and high maneuver performance. Light alloy with low density and high intensity is the best choice of the AMDR flame-proof encloser material.

ZL401 cast aluminium alloy could be used for the shell of the coal electric drill which is the only alloy known currently. Compared with cast steel shell, the cast aluminium alloy encloser is less than half of it in weight in the same intensity. However, the cast aluminium alloy encloser need to further friction spark test. There is no special alloy for the mine robot encloser currently. ZL401 aluminium alloy is used as the mine robot flame-proof encloser material temporarily. Now, a lot of measures are taken to reduce the possibility of a collision in the design of mine robot (Zheng 1990, Li et al. 2009).

3.2 *The flame-proof encloser shape design of the AMDR*

Flame-proof encloser demands its volume so smaller that it can go through the narrow space in the tunnel. There also should have enough space to equip electrical components inside and have enough wall thickness to guarantee the strength. Meanwhile, we should consider the heat dissipation problem in the flame-proof encloser shape design of AMDR. For the above problem, the safety of the robot is the most important at all. So, the strength of flame-proof encloser must be considered firstly.

In the explosion process, the explosive mixtures combust and expand around at the same time. The pressure wave transfers to the air in sphere. In the same volume, the explosion pressure is changeable with different encloser shape because of the heat dissipation area and speeds of flame-proof encloser is different. Since there is no any obstacles, pressure waves impact spherical encloser inner wall almost at the same time. The sphere encloser

bears the higher pressure right now. If the pressure wave reaches all parts of inner wall in a longer time lag, inner wall absorb more explosive energy. The impact on the encloser wall is smaller. So, the more complex the shape of encloser will be, the better the isolation effect will be. There are four different shape container internal comparison of explosion pressure in Table 1. As you see, cuboids container is the minimum compression and sphere is the maximum. According to the requirements, cuboids are the best shape of flamer of encloser.

But, the interior space of cylinder is bigger than cuboids in the same surface area. In case of the same quality of material, the internal space of cylindrical encloser is bigger and the intensity of encloser is higher than cuboids. And the internal stress distribution is more uniform. The flame-proof encloser adopted cylindrical shape after having a comprehensive consideration for the robot safety, mobility. The flame-proof encloser is modified at the bottom to improve the robot motion performance.

We built the model of flame-proof encloser and had finite element analysis with Solidworks after its design had been completed. The structure of the flame-proof encloser is optimized based on the results of analysis. Figure 1 shows the stress diagram of cast aluminium encloser. Flame-proof encloser reduced the weight through reducing too much local stress reserve to improve the mobility of the robot after optimization.

Table 1. Under the same volume of different shape of pressure vessel explosion.

Shape	Volume (L)	Pressure ($\times 10^5$Pa) (CH_4 9%–10%)
Sphere	8	7.1
Cube	8	6.1
Cylinder	8	5.5
Cuboids	8	5.1

* From Principle of explosion-proof.

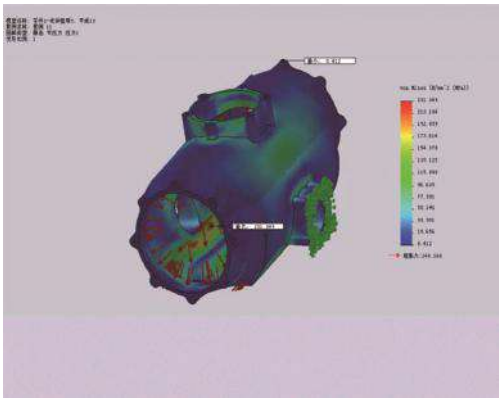

Figure 1. Stress diagram of cast aluminium enclosure.

3.3 *The flame-proof encloser structure design of the AMDR*

There are two kinds of the flame-proof structure encloser design of the AMDR. One is the relative motion of kinematic pair flame-proof structure, and the other one is no relative motion of the tightness of flame-proof structure design.

Figure 2 shows the flame-proof structure of the drive shaft. The drive shaft output drive power outward through the flame-proof encloser. The flame-proof design of the shaft should have two flame-proof joints. One flame-proof joint is formed by the surface of driven shaft and isolation bearing cover inner hole, named a. The other one flame-proof joint is formed by the surface of bearing end cover and encloser, named b. There are sealing between the shaft sleeve and flame-proof encloser, and between the drive shaft and the shaft seat ring to prevent water into the flame-proof encloser.

There are three tightness flame-proof structures. Three flame-proof joints are all combined with the surface of the two fastening together with the bolt as Figure 3, Figure 4 show. The Figure 4 shows windows design that toughened glass with flange clamp is installed in the head. Adopts toughened

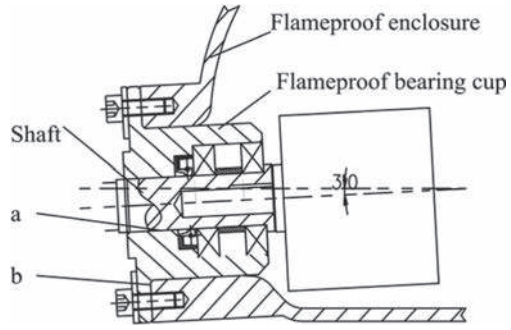

Figure 2. Flame-proof structure of the drive shaft.

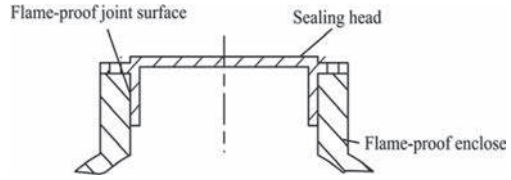

Figure 3. Schematic diagram of sealing head structure.

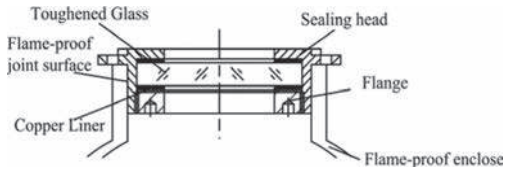

Figure 4. Schematic diagram of sealing head window structure.

glass with explosion-proof standards, add a gasket made of red copper between shell cover and toughened glass to avoid explode.

4 THE WALKING MECHANISM DESIGN OF THE AMDR

The AMDR must be flexible and good at climbing obstacle due to the mine terrain is complex. The wheeled walking mechanism possesses good manoeuvrability, high efficiency and simple structure. The tire grounding area is increased through adopting All-wheel-drive (AWD) models to obtain all terrain adaptation wheel structure (Zhu & Chen 2009). The AMDR adopts six-wheel drive, increasing contact point with the ground, avoiding the phenomenon of the robot drive wheels overhead, increasing the terrain adaptability, also reducing the weight.

4.1 *The drive mechanism design of the AMDR*

As Synchronous belt transmission ratio is accurate which can satisfy the requirement of detecting robot flexible mobility. Robot adopts synchronous belt transmission mode with one power output shaft on each side. Compared with all motor driven, it can reduce motor number and the flame-proof joint number, optimize the stress distribution of flame-proof encloser, increase internal space improve the AMDR's mobility and safety greatly. Synchronous belt is closed in a confined space, avoiding friction sparks produced, improving the safety of the robot.

In order to ensure stability in movement, reduce inertia collision in motion sudden changes, the damping system is joined between walking mechanism and flame-proof encloser shown as Figure 5. Damping system absorbs most of impact energy using polyurethane rubber rods, decreases amplitude of the flame-proof encloser, reduce sparks of collision.

4.2 *The wheel design of the AMDR*

The AMDR's tire and wheel requires explosion-proof capability relative to the ordinary which

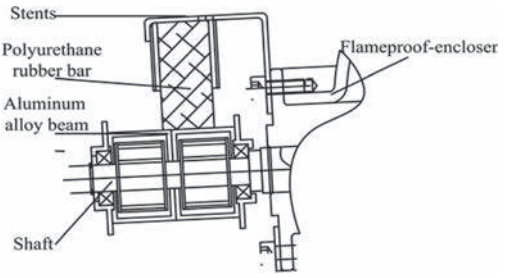

Figure 5. Schematic diagram of damping system.

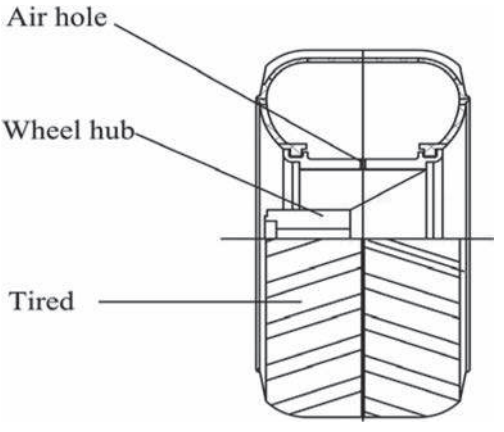

Figure 6. Schematic diagram of wheel structure.

have enough strength and grip, and wear resistance, aging resistance. So, the AMDR tire material chose oil-resistant nitrile butadiene rubber, it owns well elasticity and water resistance, oil resistance, aging resistance and strong load. Wheel hub is made of nylon added flame retardant. Tyres are designed as hollow non-pneumatic, drilling hole through the wheel hub to connect with the atmosphere. When the ground changed suddenly, tire occur deformation for shocking. The air in the tires flows rapidly through holes. Then the tire fills gas again quickly with elastic recovery and as shown Figure 6. This design increases the AMDR damping system, reduces the probability of spark collided with the ground and improves the explosion-proof performance further.

5 THE COMMUNICATION SYSTEM DESIGN OF THE AMDR

The recent studies shows that the key is put on the selection of transmitting frequency and power of radio equipment in the environment with existence of gas to ensure that the temperature is not

higher than 150°C when continuous operating in the environment with a certain mass of coal dust to prevent from fire damp explosion. Therefore, the transmitting frequency of radio equipment should be higher than 450 MHz to guarantee the safe (Yang 2008). The radio transmission is great influenced by the shape of the tunnels. In straight tunnel, if frequency is higher, attenuation rate is smaller, and it is beneficial for EM waves to transmit. In curved tunnels, it decay rapidly, and it is unfavourable for EM waves to transmit. The studies show that 900 MHz is optimal frequency for radio communication in mine tunnel (Sun et al. 2005).

The AMDR is equipped with the single-chip 433/868/915 MHz transceiver nRF905 whose maximum transmitted power is 10 mW. The frequency point needs not to apply for because the stipulation made by State Radio Monitoring Centre is conformed. The requirement of underground radio equipment is met too which is made by the SAWS. It is reliable, small, light, strong anti-jamming capability and low error rate.

6 CONCLUSION

With the development of national economy, there are more and more abandoned mines in various reasons. These abandoned mine will not only cause huge waste of resources, but also do great harm to the environment and society if the management is not properly. The re-exploitation of abandoned mine is imperative. The research of the robots replacing human in abandoned mine has very broad prospects. The research focuses on the explosion-proof performance of the encloser, walking mechanism and communication method under the situation of flooded shafts or collapses. Meanwhile, this paper provides the reference for the safety design of the mine robot in the future.

ABSTRACT: In order to get the regulation of water hazards and to supply for the future water prevention work in Yima Coalfield, the historic data, geological structure, the distribution of small coal mines, the river region, the main aquifer and aquifuge, mining thickness and the fissures have been analyzed systematically. With small coal mines closure, treatment of fissures and channels, and the deeper mining activities, the main water hazards have changed from precipitation, surface water and kiln water into roof flood. The threat of the roof water mainly happened on the core of syncline with 700 m deep and also happened on the edge of fault and the rich abundance region. Roof water inrush has close relationship with mining thickness and periodic mine pressure. For roof water hazard, "three maps-two predictions" was proposed and applied in evaluation and prediction of water inrush source, channel and intensity. With geophysical prospecting, the suspected water rich area has been obtained and then the drainage work could be done before mining. Besides, other water prevention work which can improve the drainage capacity of the working face also should be carried out.

1 COALFIELD SITUATION

Yima Coalfield is the only Jurassic continental coalfield in Henan with the area of 100 km^2. The coalfield is located on the west poor water area in Henan, across the country of Yima and Mianchi. The whole coalfield is shown as an asymmetric syncline. It starts from the outcrop of coal seam in the north and disappears on the edge of reverse fault F_{16} to the south. Both of the east and west boundaries are missing as sedimentation. The minable seams distribute in the Middle Jurassic Yima Group including 5 layers in 2 groups. Respectively, they are 1–1 seam and 1–2 seam; 2–1 seam, 2–2 seam and 2–3 seam from above to bellow (WANG Yun-quan & MENG Fan-shun 1994, WANG Yun-quan, et al. 1990). The total thickness of coal seam is about 3~40 m. Its rank is long flame coal with 2~1200 m depth. The land surface is hills with south higher than north. The layers which are mainly gravel, sandstone and mudstone with no rich aquifers dip south by east.

There are five coal mines and one opencast coal mine in Yima Coalfield (Fig. 1). The annual production of raw coal is about 1.3×10^7 *t*. The total production of coal is about 2.3×10^8 *t* and the current coal resources are about 4.5×10^8 *t*. After mining for several years, each coal mine has turned to the 2# coal seam where the maximum depth is 1040 m. Rock burst, spontaneous combustion of coal seam and water hazards are the main disasters in Yima Coalfield (XIA Yong-xue, et al. 2011, ZHAO Shan-kun, et al. 2012, PAN Jun-feng, et al. 2012, MU Hong-cai 2005, LI Jian-xin 2006, DU Dong-jian & MA Xian-chao 2012, ZHAI Er-an 2005). Compared with the former, the study on water hazards is shortage.

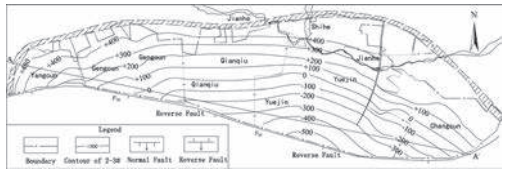

Figure 1. Distribution of coal mine in Yima Coalfield.

2 HYDROGEOLOGICAL CONDITIONS

2.1 *Precipitation and Surface Water*

The local average annual precipitation is about 670 mm with the flood season lasting from July to September. Jianhe and Shihe are seasonal rivers which flow though the east of the coalfield. They cross Qianqiu, Yuejin and Changcun Coal Mines which are the main surface water. Shihe dries up most of the time in the year and the maximum flow is 100 L/s in rainy season. Jianhe sometimes dries up, but its maximum flow had ever reached 1446.5 L/s. Precipitation is the main supplies for each aquifer through the fissures on the ground in shallow coal field. The surface river provides sufficient water by fissures, collapse and artificial channel. As small coal mines closure, treatment of fissures and collapses, and deeper mining activities, the impact of precipitation and surface water become smaller on the coal mines.

2.2 *Main aquifers*

The main aquifers are as followed (Fig. 2).

The Middle Jurassic Sandstone Fractured Confined Aquifer. It is above the coal seam with distance of 4.0~54.0 m. The layer consists of packsand, sandy mudstone and conglomerate with the average thickness of 180 m. The gravels mainly contain quartzite, quartz sandstone and limestone. The water yield property is relatively weak and this aquifer is the direct water bearing strata. The water quality type is HCO_3^-Na·Ca. The permeability coefficient is 0.000405~0.0322 m/d and the specific capacity is about 0.00007~0.00622 L/(s·m). This aquifer doesn't have the identical water level with poor connection. In the shallow parts, it is supplied by precipitation and river. Currently, its discharge form is drainage.

The Upper Jurassic and Cretaceous Gravel Fractured Confined Aquifer. The thickness of the layer is 0~880 m with the average thickness of 467 m. The gravels are mainly quartz sandstone and limestone with poor sorting features. The water yield property is weak for high cementation. In some parts of the aquifer, the water yield property is well for fissures developing. The water quality type is HCO_3^-Ca. The permeability coefficient is 0.2~1.47 m/d and the specific capacity is about 0.0626~0.178 L/(s·m). This aquifer mostly receives water from Neocene layers while the south region receives precipitation. Its discharge form is drainage.

The Neogene Mudstone Confined Aquifer. The thickness is about 0~50.8 m with the average thickness of 10.3 m and water yield property is moderate. The water quality type is HCO_3^-Ca.

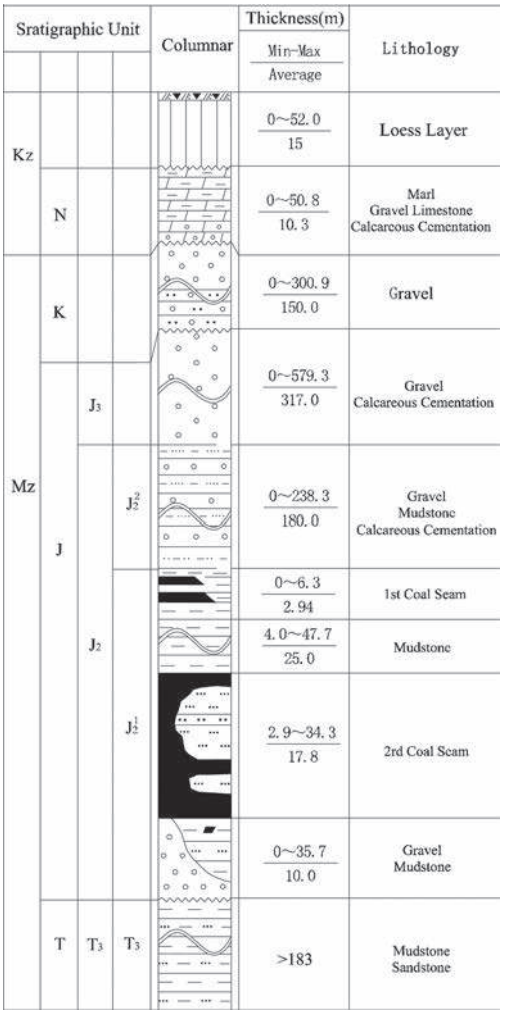

Figure 2. Stratigraphic columnar in Yima Coalfield.

The permeability coefficient is 0.22~206.1 m/d and the specific capacity is about 0.0695~0.455 L/(s·m). This aquifer receives the precipitation and Quaternary phreatic water with big seasonal change. Currently, the pumping is its discharge form.

The Quaternary Gravel Phreatic Aquifer. The thickness is less than 2 m and the water type is HCO_3^-Ca. The permeability coefficient is 0.22~206.1 m/d and the specific capacity is about 0.029~6.71 L/(s·m). This aquifer receives precipitation and river with big seasonal change.

2.3 *Main aquifuge*

The Middle Jurassic mud aquifuge of the 2nd coal seam roof is about 4.0~54.0 m with 28.0 m on

average, which is the direct roof of the 2nd coal seam (Fig. 2). The destruction on surrounding rocks caused by excavating roadway is limited and the layer is able to prevent the water. However, the fissures would access to the overlying aquifer after mining, which lead to the poor prevention of the aquifuge.

3 REGULATION OF WATER HAZARDS

According to the statistics, 79 times water inrush have been happened in Yima Coalfield. According to the source of water, the roof sandy conglomerate water is of 48.1% with 38 times; the goaf water is of 43% with 34 times; the surface water is of 8.9% with 7 times. According to the intensity of water inrush, the outsize inrush and large inrush accidents are each 3 times of 7.6% which water sources are surface water. Others are middle and small intensity which water sources are roof gravel water and goaf water. In the view of time, various types of water inrush accidents had happened before 1997. Nevertheless, the roof conglomerate water inrush is the main type after 1997, which the water bursting water quantity is about 6~450 m^3/h (Table 1).

3.1 *Precipitation and phreatic water*

Precipitation is the main factor of water filling in Tianxin Coal Mine (opencast coal mine). The mining elevation of other coal mines is about 200 m while the depth is less than 300 m in general. After mining, the fissures would extend to the limestone in Neogene, unconsolidated layers in Quaternary and even to the land surface. The precipitation could fill into mines through the fissures. Sometimes, the Neogene and Quaternary phreatic water could also be filled by same channels. The water inflow showed obvious seasonal changes in the late 1990s. As the deeper mining activities and treatment of collapse and fissures in recent years, the effect of precipitation becomes small. Meanwhile, the water inflow didn't show seasonal changes.

3.2 *Surface water*

As for enough waterproof coal pillars, Jianhe and Shihe don't directly supply the coal mines. But with the small coal mines mining along the rivers in 1980s, the waterproof coal pillars have been broken, which made the surface water become the main hazard (LI Song-ying, et al. 2003). During the flood season, the surface water caused lots of flooded accidents (Table 2). The region which was threatened by surface water showed zonal distribution along Jianhe and Shihe. However, Gengcun and Yangcun haven't been affected by surface water. With small coal mines closure and treatment of collapse and fissures, the influence of surface water is limited.

3.3 *Kiln water*

According to the statistics, there are more than 700 kilns in Yima Coalfield within the elevation of 200 m. Before the 1990s, the kiln water was the main factor for water filling of coal mines as each coal mine accessed to the goaf area. With the deeper mining activities and small coal mines closure, the threat of kiln water had been weakened.

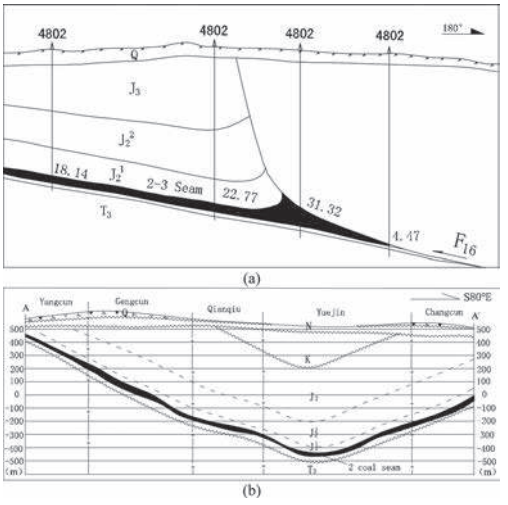

Figure 3. (a) Geological profile of 48 line; (b) Geologic section in deeper trend in Yima Coalfield (AA′).

Because the goaf areas connected to the big coal mines and the channel was clear, the upper goaf areas could not accumulate a lot of water.

3.4 *Roof water*

During the shallow mining, roof water flows into coal mines with trickling or bursting with small intensity, which didn't affect the production. As deeper mining, the frequencies of roof flood and water inflow increased obviously, which severely affected the production and even threatened the working face (Table 2). For example, roof flood had been occurred in the working face 25080 of Yuejin coal mine as it accessed to the F_{2-3}. The normal water inflow was about 10 m^3/h while the max water inflow was about 450 m^3/h. Finally, the inflow dropped to about 150 m^3/h after 100 days and the whole quantity was more than 2.6×10^6 m^3. The working face 21172 of Qianqiu coal mine crossed a fault and the max water inflow was more than 300 m^3/h with a steady quantity of 200~250 m^3/h. By the end of June 2013, the total amount was about 3.8×10^6 m^3.

The regulation of roof water hazards in Yima Coalfield are as followed:

The roof water hazards happened below the elevation of −50 m and mining depth is over 700 m. In this area, the water yield property is much stronger as the area is around the reverse fault 16# and the syncline core (Fig. 3). Besides, the thickness of conglomerate in this area is more than 400 m with strong water capacity. Yuejin coal mine locates in the core of the syncline and has been threatened by roof water. The adjacent domains between Qianqiu and Changcun are also threatened.

The water yield property of roof fractured aquifer is uneven with poor connection. In the fault zone and its tip area, the water yield property is relatively strong which could lead to water hazard (ZHANG Chunguang, et al. 2012). Once water inrush happened in a working face, the adjacent face could also be threatened.

The roof water inrush has close relationship with the periodic weighting of mining.

The roof water inrush also has close relationship with the mining thickness. The max coal thickness is more than 20 m by caving mining, which would destroy the roof seriously. According to the empirical formula, the height of roof fissure could be more than 300 m and may cross the mudstone aquifuge, the Middle Jurassic sandstone aquifer. Finally, it could be reached into the Upper Jurassic and Cretaceous conglomerate aquifer.

In the beginning of roof water inrush, the water quality type is general HCO_3^-Na. After some time, it changes into HCO_3^-Ca (Table 3). According to the change, it can be inferred that the water comes from the Middle Jurassic sandstone aquifer and then turns into the Upper Jurassic and Cretaceous gravelstone aquifer. It can be seen that why the quantity could be steady after water inrush.

4 CONTROL TECHNIQUES

4.1 *Precipitation and surface water*

The shallow part of coalfield, river and its terrace should be patrolled regularly. The collapse and ground fissures should be filled in time.

Table 3. The comparison of water quality before and after water inrush.

	Previous period	mg/l	meq/l	meq%	Later period	mg/l	meq/l	meq%
Cation	K^++ Na^+	184.11	7.36	83.6	K^++ Na^+	20.11	0.80	6.30
	Ca^{2+}	19.64	0.49	11.1	Ca^{2+}	105.81	2.64	41.6
	Mg^{2+}	4.86	0.20	4.60	Mg^{2+}	79.49	3.27	51.6
	NH_4^+	1.00	0.06	0.70	NH_4^+	1.00	0.06	0.50
Anion	Cl^-	35.10	0.99	11.30	Cl^-	44.67	1.26	9.90
	SO_4^{2-}	48.03	0.50	11.40	SO_4^{2-}	56.68	0.59	9.30
	HCO_3^-	392.36	6.43	73.1	HCO_3^-	613.86	10.06	79.4
	CO_3^{2-}	11.35	0.19	4.20	CO_3^{2-}	5.40	0.09	1.4
PH		8.00			PH	7.60		

4.2 *Kiln water*

The small coal mines which were closed should also be patrolled regularly. Once there are unfilled shafts, collapses and fissures, the treatment should be carried out in time.

4.3 *Roof flood*

The treatment of roof flood is the key and difficulties in the future in Yima Coalfield.

The regulation of water yield property and water inrush should be deeply studied for water prevention. Firstly, the distribution of water rich area could be obtained by the method of "three maps-two predictions" and the study of structure. Secondly, the distribution of roof safety area could be got by the thickness of aquifuge, mining thickness and the height of fissures. Finally, the water origin, channel and the intensity of the roof flood could be predicted and evaluated by the comprehensive map (LIU Wu-tao, et al. 2001, WU Qiang, et al. 2013, WU Qiang, et al. 2000, WU Qiang, et al.2010, WU Qiang, et al. 2011, LIU Wei-tao, et al. 2007).

The geological structure and water yield property in working face could be detected by 3-D seismic exploration and transient electromagnetic prospecting. The suspected area could be obtained by analyzing the data of geophysical prospecting (WANG Wei, et al. 2012, YU Jing-cun, et al. 2011, LIU Yunqi, et al. 2009).

Before mining, the suspected water rich area could be drained. It could reduce the affect of roof water during the production.

Before mining, drainage system should be built. The capacity of water drainage in mining area should be improved. Track roadway is the key to waterproof and drainage of working face. It would be tunnelled in positive slope as far as possible with inside high and outside low, which can avoid flooding of roadway or working face after roof flood.

5 CONCLUSIONS

Various types of water hazards exist in Yima Coalfield, including precipitation, surface water, kiln water and roof flood. With small coal mines closure, the treatment of river and ground fissures and deeper mining activities, the main water hazard has changed into roof flood. The treatment of roof flood would be the key and difficulties in the future in Yima Coalfield. For roof flood, the source, channel and the intensity can be predicted and evaluated by "there maps-two predictions" with the study of water yield property. The suspected water rich area could be found by geophysical prospecting and then water drainage could be carried out. The water drainage should be the main work to prevent roof flood, meanwhile, it is also important to improve the capacity of drainage system in working face and enhance the ability of water resisting.

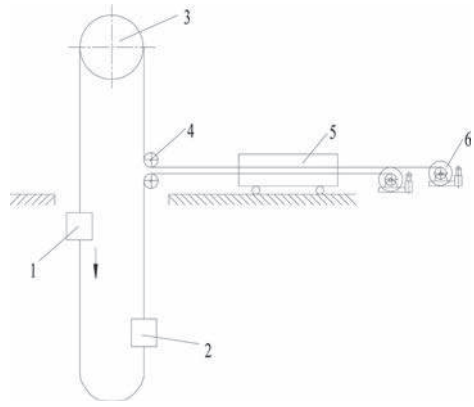
The safety technology of head rope replacement in large friction hoisting mine

A.T. Balkema & G. Westers
A.A. Balkema Publishers, Rotterdam, The Netherlands

Meng-Juan Dong & Fu-Yin Jia
College of Energy Sources and Safety, China University of Mining and Technology, Xuzhou, Jiangsu, China

ABSTRACT: The head rope exchange work is frequently in friction hoist mine. Due to the backward rope exchange technology and equipment, the work is difficult and time consuming, and has many potential accidents, quite easy to cause casualties. First put forward the rope exchange method of interactive rope exchange vehicle, establishing the statics model of interactive rope exchange system. Determine the mechanical properties of rope exchange system, developed the safety rope exchange vehicle suit for the rope exchange work in mine. And assay its properties. Under the premise that the tension of hoist system head rope unchanged, the equipment can realize the synchronous swaps of the new and old head rope at wellhead, achieve high velocity, safety, and environment adaptive capacity. And is of great significance to protect the safe and efficient production of mine.

Keywords: head rope, replacement, rope exchange vehicles, statics



1 OUTLINE

In friction lifting mine, Hoisting System run by the friction between the head rope and the friction wheel, the safety and reliability of the first line directly affect safety. According to "coal mine safety rules", the head rope needs to be replaced every 2 years, if broken wire, corrosion, wear is overrun, rope diameter shrinkage exceed limit, and so on appeared on the head rope, it must be replaced in time, even if less than two years.

At present, the tool used in the head rope replacement in our country is relatively backward, operation time is long, large labor intensity, workers in hazardous area working frequency is high, the probability of an accident is big, and the old and the new head rope connection with card, easy to cause new head rope damage (Jia F Y & Dong M J 2011, Zuo Y Q & Jia F Y 2011, Ma K C & Jia F Y 2011, Ma K C & Jia F Y 2011). This is especially ture in large coal mine, the rope replacement work need 40–50 people, 3–7 days every time. With the increasing of mining depth, mine exceed ten million tons becoming more and more, the diameter of wire rope exceed 60 mm in some mines. If the rope replacement is still using the original method, it takes not only the low efficiency, but also the high risk. Therefore to ensure hoisting safety, study on the head rope replacement is of great significance.

2 METHOD OF EXCHANGING THE NEW AND OLD ROPE

The method of exchanging the new and old rope worked by the rope exchange vehicle. As showed in figure 1, let a cage in the bottom, the other in the wellhead, fixed the bottom cage at wellhead, disassembly the Container tent, head rope and the

1-cage1; 2-cage2; 3- friction wheel; 4- guide wheel; 5- rope exchange vehicle; 6-pull and put rope hoist

Figure 1. . Schematic of replacing ropes.

Wedge wire ring, use messenger lead in the new rope, then connect the cage by Wedge wire ring (Ma K C & Jia F Y 2011). Rope exchange vehicle straining the new and old head rope, draw the cage in bottom to wellhead. Remove the shed, start the winch, release the wellhead cage to bottom. Draw the bottom cage to the wellhead, disassemble the Container tent at wellhead. Lock the new head rope at the other side, remove the head rope of the wellhead cage, relieve the Wedge wire ring, draw the new head rope and assemble the Wedge wire ring and connect the wellhead cage, start the winch, remove the shed after the wellhead cage was drawed, arrive here, rope exchange work is complete.

This method cooperate the rope exchange vehicle can realize the function of sending new rope and drawing old rope automatically. Implements all operations accomplished at wellhead, quick and convenient, the operator and accident potential less than before, achieve high safety and efficiency.

3 STATICS MODEL OF TOWER-TYPE REPLACING ROPE SYSTEM

As Mi for quality of cage; mi for quality of rope; e for napierian base, e = 2.718; μ for friction factor; α f or the circumference angle between wire rope and friction wheel; σ for antislip safe coefficient; Fi for wire rope tension.

1 Static condition

Point c wire rope tension:

$$F_c = m_1 g + M_1 g + m_3 g$$

Point d wire rope tension:

$$F_d = m_5 g + F_a$$

When

$$F_c > F_d$$

The tension difference on both sides of the friction wheel:

$$F_c - F_d$$

The limit friction between rope and the friction wheels:

$$f_{m1} = F_d(e^{\mu_1 \alpha} - 1)$$

The rope and the friction wheel will not occur for sliding conditions:

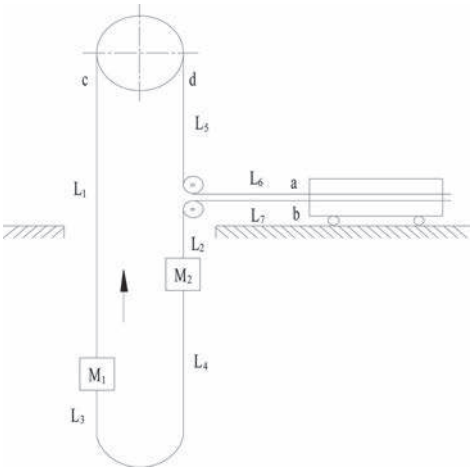


Figure 2. Statics model of tower-type replacing rope system.

$$F_c - F_d < F_d(e^{\mu_1 \alpha} - 1) / \sigma_j$$

Have

$$F_a > (m_1 g + M_1 g + m_3 g) / [(e^{\mu_1 \alpha} - 1) / \sigma_j + 1] - m_5 g \quad (1)$$

When $F_d > F_c$,

$$F_d - F_c < F_c(e^{\mu_1 \alpha} - 1) / \sigma_j \quad (2)$$

$$F_a < (m_1 g + M_1 g + m_3 g)\left[(e^{\mu_1 \alpha} - 1) / \sigma_j + 1\right] - m_5 g \quad (3)$$

Have

$$(m_1 g + M_1 g + m_3 g) / \left[(e^{\mu_1 \alpha} - 1) / \sigma_j + 1\right] - m_5 g < F_a < (m_1 g + M_1 g + m_3 g) \left[(e^{\mu_1 \alpha} - 1) / \sigma_j + 1\right] - m_5 g \quad (4)$$

Point b wire rope of static tension:

$$F_b = M_2 g + m_2 g + m_4 g$$

2 State of uniform acceleration

Set the acceleration to a Point c wire rope tension: $F_c = (m_1 + M_1 + m_3)(g + a) + F_z$, as F_z for Mine hoists resistance;

Point d wire rope tension: $F_d = m_5(g - a) + F_a$

$$\left[(m_1 + M_1 + m_3)(g + a) + F_z\right] / \left[(e^{\mu_1 \alpha} - 1) / \sigma_d + 1\right] - m_5(g - a) < F_a < \left[(m_1 + M_1 + m_3)(g + a) + F_z\right] \times \left[(e^{\mu_1 \alpha} - 1) / \sigma_d + 1\right] - m_5(g - a) \quad (5)$$

Point b wire rope of static tension:

$$F_b = (M_2 + m_2 + m_4)(g - a) - F_z$$

3 Uniform state

Point c wire rope tension:

$$F_c = m_1 g + M_1 g + m_3 g + F_z$$

Point d wire rope tension: $F_d = m_5 g + F_a$

$$\begin{aligned}&(m_1 g + M_1 g + m_3 g + F_z) / \left[(e^{\mu_1 \alpha} - 1) / \sigma_d + 1\right] \\ &- m_5 g < F_a < (m_1 g + M_1 g + m_3 g + F_z) \\ &\times \left[(e^{\mu_1 \alpha} - 1) / \sigma_d + 1\right] - m_5 g \end{aligned} \quad (6)$$

Point b wire rope of static tension:

$$F_b = M_2 g + m_2 g + m_4 g - F_z$$

In a mine for example, parameters are as follows:

head rope: 6.535 kg/m; 840 m; 4 root
tail rope: 9.954 kg/m; 782 m; 2 root
skip: 23.67 T
friction coefficient: backing 0.3
Anti-slip coefficient: 1.75 (static); 1.25 (motion)

When exchange the rope, the hoist started with rope exchange vehicle, The difference tension on both sides of the drum is 0, have

$$F_a = (m_1 + M_1 + m_3)(g + a) - m_5(g - a) + F_z \quad (7)$$

$$F_b = (m_2 + M_2 + m_4)(g - a) - F_z \quad (8)$$

$$F_a = F_b = \frac{105206}{4} = 26301N$$

Table 1. The rope static tension when the left skip at bottom hole.

	F_a	F_b
Static condition	105206	94182
State of acceleration	109819	89741
Uniform state	101726	90702

Table 2. The rope static tension when the left skip at wellhead.

	F_a	F_b
Static condition	94182	105206
Retarded state	97631	102800
Uniform state	97661	101726

So the rope tension release of rope exchange vehicle as long as more than 26301 N.

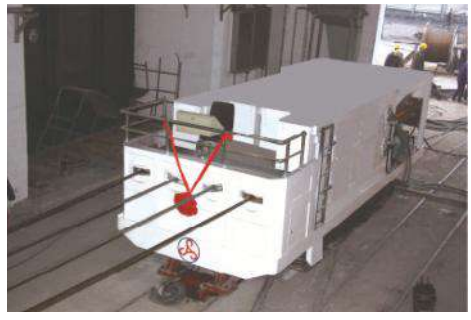
4 COMPOSITION AND TEST OF ROPE EXCHANGE VEHICLE

4.1 *The composition of rope exchange vehicle*

The rope exchange vehicle is a collection of a pull system, and rope winch, protection system and power system, able to apply all replacement, maximum release speed can reach 0.5 m/s, greatly save the rope release time. When the method of exchange rope in appropriate cases, can exchange rope work done within 12 hours in mine, which 1000 m deep and the head rope more than 40 mm in diameter. And release rope are implemented by high-quality friction liner, old and new head line tolerance status the same as the friction roller, do not damage the head rope. As shown in figure 3.

4.2 *The tensile test of rope exchange vehicle*

The pulling force of rope exchange vehicle is the key to implement the old and new head rope syn-



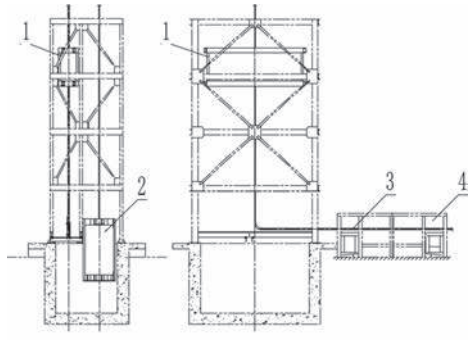


Figure 3. The photo of rope exchange vehicle.

	Put rope force (KN)	39	48	56	68	75	96	102	109	114

chronous interaction exchange on wellhead, so according to the actual parameters design of mine, the test will determine the pulling force. As shown in figure 4. Connect the test cage and the balance weight, test cage side weight is greater than the balance weight side. Requirements in under the action of no external force, cage rely on gravity to run down. Load the clamping cylinder pressure ceaselessly, stop the pressure when the rope slide in the unit, the force is under different clamping pressure corresponding to the pulling force of rope exchange vehicle. According to table 4, the pulling force of rope exchange vehicle were greater than 26301 N, meet the requirements.

5 PRACTICAL APPLICATION

Under the premise of head rope tension unchanged in hoisting system, the new and old rope interactive rope exchange vehicle rope exchange technique to realize the new and old rope Synchronous swaps wellhead. Solved the problem which previous rope replacement work labor force intensity big, long operation time, risk degree is high, and easy to appear the accident in mine. The pull system of rope exchange vehicle can meet the requirements of mine for the pulling force, and release rope are implemented by high-quality friction liner, do not damage the head rope; The security protection system can effectively avoid the elevator carry overrun, ensure the safety of the elevator running provides guarantee for mine safe and efficient production.

ABSTRACT: The oxidation at low temperature (T ≤ 70°C) is the key process on researching the coal spontaneous combustion. Due to the lower oxidizability of anthracite coal than other types of coal, most researches about coal spontaneous combustion were centered on the higher temperature, but few on lower temperature. C80 micro calorimeter was applied to investigate the heat flow of Kabuliang anthracite coal with different temperature rising rates (0.1°C/*min,* 0.2°C/*min* and 0.4°C/*min*) from room temperature to 200°C, it was found that the heat release process of anthracite coal took place before 40°C. Based on Popescu non-model method, the mechanism functions and kinetic parameters were analyzed, the result indicates that oxidation reaction of Kabuliang anthracite coal corresponds to the anti Jander equation controlled by the three-dimensional diffusion model at 40–70°C, the value of activation energy is 72.81(KJ/mol) and the value of pre-exponential factor is 53903.35(s^{-1}).

Keywords: Anthracite coal, Coal oxidation at low-temperature, Popescu method, Kinetics

The anthracite coal with low ash and sulfur is superior coal resources, although it is a kind of high rank coal, it also occurs spontaneous combustion[1]. Spontaneous combustion of coal is a complicated process of the reaction between coal and oxygen, which includes the oxidation process at low temperature (T ≤ 70°C) and accelerated reaction process (T ≥ 70°C), and the oxidation process at low temperature is the key process of the coal spontaneous combustion prevention and the mechanism research[2]. Because of the weaker oxdability of the anthracite coal at the low-temperature oxidation process than other types of coal, most researches about the character of anthracite coal spontaneous combustion is still on accelerated reaction process, but few in low-temperature oxidation process[3–9]. For the research of reaction mechanism function, thermal analysis technique is widely used because of the advantage on test speed and repeatability. However, the common thermal analysis apparatuses such as DSC and DTA are hard to get accurate changes of heat and mass with the small test mass and high temperature heating rate, which has restricted the research on mechanism function of low-temperature oxidation process[10]. In recent years, along with the development of micro calorimeter, it has become an efficient way to investigate the coal low-temperature oxidation process depending on its advantages of larger test mass, lower temperature heating rate and higher test precision[11]. C80 micro calorimeter was used to investigate the low-temperature oxidation mechanism of anthracite coal.

1 EXPERIMENT

1.1 *Sample coal*

Kabuliang (KBL) anthracite coal was used as the test coal sample, it was transported to the laboratory sealed perfectly after collecting from the coal mine. Coal was broken into pieces under the protection of nitrogen, and then, the part of particle

Table 1. Proximate and ultimate analyses of the coal sample.

Coal sample	Proximate analysis (dry basis)				Heat	Ultimate analysis (dry basis)	
	Moisture (%)	Ash (%)	Volatile (%)	Fixed C (%)	Q (KJ/mol)	H (%)	S (%)
KBL anthracite coal	1.12	6.86	11.76	80.26	32.93	3.78	0.23

size ranging from 0.18–0.38 mm were sieved out to be test coal sample. The proximate and ultimate analyses of the coal is shown in Table 1.

1.2 *Experimental apparatus and process*

C80 micro calorimeter produced by Setaram corporation was used as experimental apparatus. The 500 mg coal sample and $\alpha - Al_2O_3$ were put into the reaction cell and reference cell respectively in the experiment. At the beginning of experiment, a 70 ml/min high purity nitrogen was admitted into reaction and reference cell, the coal sample was dried for 10 h in 105°C temperature control stove for getting rid of water. Then, the temperature was cooled down to 26°C under the protection of nitrogen, a 70 ml/min high purity oxygen was admitted into reaction and reference cell after temperature stabilized. The experiments were started with the 200°C as ending temperature at different temperature rising rates (0.1°C/*min,* 0.2°C/*min* and 0.4°C/*min*).

1 EXPERIMENTAL RESULTS AND ANALYSIS

2.1 *Experimental results*

The heat flow curves at different temperature rising rates of anthracite coal were shown in Fig 1, and the initial heat release temperatures at different temperature rising rates were shown in Table 2. From the Fig 1 and Table 2, before 200°C, the oxidation of anthracite coal is a process of slow heat release at lower temperature, then accelerated heat release at higher temperature. The initial temperature is lower than 40°C when using the C80 micro calorimeter, which is lower more than 40°C by using the DSC[12–13]. Thus, the heat release characters at low temperature are more accurate by using C80 micro calorimeter than DSC.

2.2 *Calculation and analysis on mechanism functions of coal spontaneous combustion*

In order to avoid the effect of kinetic compensation effect, the Popescu non-model method based on multiple scanning rates was used to determine the mechanism functions of KBL anthracite coal between 40°C and 70°C. This method not only does not use any approximate calculation of temperature intergral but also does not take any forms $k(T)$ into

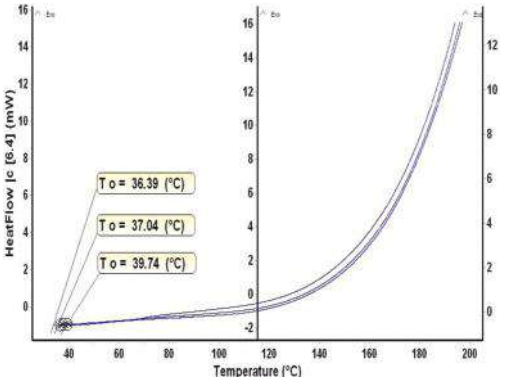

Figure 1. Heat flow curves at different temperature rising rates.

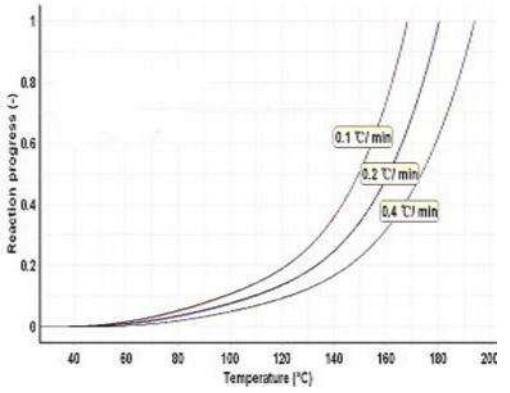

Figure 2. Conversion of KBL coal sample.

Table 2. Initial heat release temperature of KBL coal sample at different temperature rising rates.

Temperature rising rate (°C/min)	0.1	0.2	0.4
Initial heat release temperature T (°C)	36.39	37.04	39.74

consideration, which has been widely used in the research of coal combustion mechanism[14–19].

2.2.1 *Principle of kinetic mechanism obtained by Popescu method*

Popescu is a non-model kinetic analysis method which is based on multiple scanning rates[20], two temperature values $T = T_m$ and $T = T_n$ will determine a pair of values of α on each curve of different heating rate: (α_m1, α_n1)… (α_m3, α_n1), and also three pairs of T at two conversion values $\alpha = \alpha_m$ and $\alpha = \alpha_n$: (T_m1, T_n1)…(T_m3, T_n3). The basic kinetic function:

$$\frac{d\alpha}{dT} = \frac{1}{\beta} f(\alpha)k(T) \tag{1}$$

After taking the rearranging the terms, logarithms and approximate calculation, Eq (1) then becomes

$$G(\alpha)_{mn} = \int_{\alpha_m}^{\alpha_n} \frac{d\alpha}{f(\alpha)} = \frac{A}{\beta}(T_n - T_m)\exp\left(-\frac{E}{RT_\xi}\right) \tag{2}$$

Where α is the conversion; β is the temperature heating rate; $k(T)$ is the reaction rate constant; $f(\alpha)$ is the mechanism function; $G(\alpha)$ is the integral of $f(\alpha)$;

$$T_\xi = \frac{T_m + T_n}{2} \tag{3}$$

The conversion at any temperature T on the heat flow curves

$$\alpha_T = \int_{T_O}^{T} \frac{dH}{dT}dT \Big/ \int_{T_O}^{T_{end}} \frac{dH}{dT}dT = \Delta H_T / \Delta H \tag{4}$$

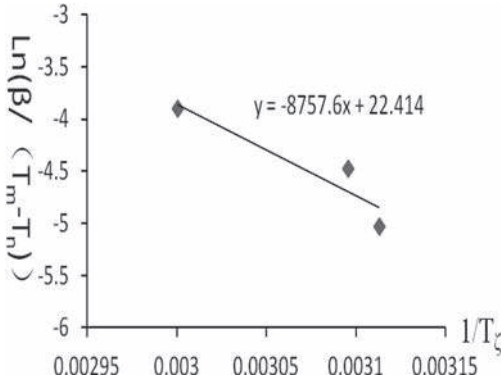

Figure 3. Plots of ln ($\beta/(T_n - T_m)$) versus $1/T_\xi$.

Where T_0 is the initial heat release temperature; T_{end} is the ending temperature; αT is the conversion at the temperature T; ΔH is the output of heat.

From Eq(2), the integral term at certain temperature T is constant, which means the plot of the values of mechanism function $G(\alpha)_{nm}$ versus $1/\beta$ has to lead a straight line with an intercept of zero. Thus, by the calculating the values α on each curve of different heating rate, the mechanism function can be determined by the plot of $G(\alpha)_{nm}$ versus $1/\beta$. If the plot of the values of $G(\alpha)_{nm}$ versus $1/\beta$ is a straight line with an intercept of zero, then the chosen $G(\alpha)$ is the mechanism function of the reaction. This method determines mechanism function with few assumption, and it also does not take the forms of k(T) into consideration, which avoids the effect of kinetic compensation effect, the analysis result has higher credibility.

2.2.1 *Mechanism function at low-temperature reactions*

According to the heat flow curves, the values of conversion α versus temperature T obtained by Eq(4) using AKTS analysis software are shown in Fig 2. Based on the principle of Popescu method, the conversion values α of three different temperature rising rate at 40°C and 70°C were put into 20 typical kinetics mechanism functions in Table 3. The linear regression method was used to analyses the scatter diagrams of $G(\alpha)_{nm}$ versus $1/\beta$. The linear regression results of mechanism functions $G(\alpha)_{nm}$ versus $1/\beta$ between 40°C and 70°C of KBL anthracite coal are shown in Table 3, where R^2 is the linear correlation coefficient which reflects the fitting degree of regression line and r_{SD} is the standard deviation which reflects the deviation between actual value and regression value. The function with maximum R^2 and minimum r_{SD} is the probable mechanism function.

Comparing the linear correlation coefficient and standard deviation for every kinetics mechanism function in Table 3, the NO.19 function is the most probable one. In consequence, the anti Jander equation controlled by the three-dimensional diffusion model is the most probable mechanism function for reaction of KBL anthracite coal between 40°C and 70°C.

2.3 *Activation energy and pre-exponential factor*

Taking logarithms, the Eq (2) becomes

$$\ln\left(\frac{\beta}{T_n - T_m}\right) = \ln\left[\frac{A}{G(\alpha)_{mn}}\right] - \frac{E}{RT_\xi} \tag{5}$$

The data of conversion and temperature were taken into the Eq (5) where $G(\alpha)$ is the function

Table 3. The linear regression results of 20 typical kinetics mechanism functions.

Number	Mechanism	Integral $g(\alpha)$	Correlation coefficient/R^2	Standard deviation/r_{SD}

19	Anti Jander function, three-dimensional diffusion	$[(1+\alpha)^{\frac{1}{3}}-1]^2$	0.971185	0.00000936
20	Three-dimensional diffusion	$[(1-\alpha)^{-\frac{1}{3}}-1]^2$	0.971295	0.00000993

of anti Jander equation controlled by the three-dimensional diffusion model, then making the scatter diagram of the $\ln(\beta/T_n - T_m)$ versus $1/T_\xi$, which is shown in Fg 3, the values of activation energy and the pre-exponential factor obtained from slope and intercept are: E = 72.81(KJ/mol), A = 53903.35(s^{-1}).

3 CONCLUSION

The heat release process of KBL anthracite coal takes place before 40°C by the test of C80 micro calorimeter, which is a process of slow heat release at lower temperature then accelerated heat release at higher temperature from the initial heat release temperature to 200°C. Based on Popescu non-model method, the mechanism functions and kinetic parameters were analyzed, the result indicates that oxidation reaction of KBL anthracite coal between 40°C and 70°C corresponds to the anti Jander equation controlled by the three-dimensional diffusion model the value of activation energy is 72.81(KJ/mol) and the value of pre-exponential factor is 53903.35(s^{-1}).

ABSTRACT: Common fire-prevention materials cannot be filled quickly and are toxic, corrosive and low efficiency. In order to solve the disadvantages of these common materials as well as to improve the efficiency of anti-extinguishing, a better coagulant was selected for developing a new type of environmentally friendly foamed gel. The results show that the dehydration rate of foamed gel accelerated with increasing temperature; The foamed gel in various stages of different temperatures meet different dynamics characters and mainly affected by the surface control and diffusion control; The complete dehydration time formula can be used to estimate complete dehydration time of foamed gel within a specific range; The differences in the physical properties made foamed gel a better evaporation-water loss rate than gel. So the new-style foamed gel is an effective anti-extinguishing material with good thermal stability.

1 INTRODUCTION

The mine fire caused by coal spontaneous combustion is always of great area and concentration. Air leakage is serious because of mining disturbance. All these unfavourable factors bring substantive inconvenience for fire prevention in goaf and threat to safety of mine (Lu & Geng 2009, Shao 2007). The technology of preventive grouting, water injection and spraying inhibitor that are widely used both in China and abroad, even dytory and three-phase foam which rose later, have a certain degree of shortage (Liang & Luo 2008). For example, due to the gravity, it is difficult for water, grouting and inhibitor to deposit high. Nitrogen and inert foam can only absorb limited heat in coal because their gas heat capacity is small and cannot be closed tightly when put out a fire (Wang, et al. 2010).

Gels possess better high-temperature resistance, stability and larger heat capacity that can reduce the temperature quickly and exclude fire source than the material mentioned above (Zhang, et al. 2002). But it still has some insufficient such as the great material consumption, difficulty in underground transportation; inappropriation for large area backfilling due to its tendency to solidify when diffuse certain distance in goaf; contamination to underground environment because of the ammonia of coagulant. Foam fire-fighting technology can make material cover the whole goaf in short time come true due to its fluidity. Foamed gel is the combination of foam and gel so it possesses the fire-fighting characters of both: the foamed gel first fill the coal mined-out area by the character of flow (Bober M, et al. 1997) and then, after the foams burst, it has a better effect in plugging wind by coving the coal evenly where reflects the character of gel (Cao & Tian 2009). Beyond that, foam gel has better material utilization than gel, so it can form larger filling volume with equal quality of material. So far, the foamed gel is widely used in area of oil while merely in coal so the research of it as mine fire-fighting material is deficient. Foamed gels developed till now are ammonia or corrosive to both machines and operators due to the acidic or alkaline coagulant (Yu & Jia 2012). So the new-style foamed gel have obvious advantage and broad application prospects.

The water steam from foamed gel in high temperature reduces the concentration of O_2 and lower environment temperature as well as prevents fire rekindling in the same time (A.M. Tafreshi & M. di Marzo 1999). The effect of steaming makes gel absorb a lot of heat so the inner temperature of gel is not high and its inner structure can stay stable (Sui 2007). Just as some researchers think that the gel is better due to its lower dehydration rate than water in isolating large area fire. But there are bare reports about the evaporation character of these material or related references (Xu, et al. 2003) about character parameters about some of

them so far. In order to make good use of the physicochemical properties of it and offer thermal stability to mine coal-mine fire, the thermal stability (Luo, et al. 2007) of foamed gel is studied and its rule is summarized by implying chemical kinetics (RETUERT, et al. 2004) and heat-transfer characteristic (Tian, et al. 2010).

2 MATERIALS AND METHODS

2.1 *Materials and equipment*

The new-style foamed gel is mainly made up of four parts: base stock, coagulant, foaming agent and water. Among them, the base stock is sodium silicate whose Baume number, modulus and density is 42.16, 3.3 and 1.40 g/cm^3; the water is tap water that is not distilled and filtered considering the practical water-using condition of mine; A, B, C and D are four kinds of ammonia-free coagulant selected roughly. Among them, A and B are Lewis acid containing 3-price cation while C containing 1-price cation. D is a kind of low-corrosive organic acid. Equipment contain digital blast drying oven (GZX-9023MBE), electronic balance (BS2202S), self-assembled foam-making device etc.

2.2 *Methods*

2.2.1 *The selection of coagulant*

Coagulant is very important to foamed gel because parts of the coagulant may output a lot of NH_4 in the chemical process or is corrosive to both workers and equipment due to their own characters such as acidic or alkaline. What is more, coagulants also influence fire prevention, extinguishing and mechanical properties of foamed gel largely.

Four kinds of foamed gel named a, b, c and d respectively containing coagulant A, B, C and D are produced by foam-making device. The results show that foamed gel made by coagulant A and B have worse thermal stability and strength and their structure made by aeration process of machine are easy to loosen and collapse due to the thin foam wall. While the foamed gel made by coagulant C and D possess thicker foam wall, better mechanical properties and stronger strength than the two foamed gel mentioned above. Then set c and d in 10°C for 20 d and weight them every 24 hours and compare their dehydration rate. The dehydration of material is:

$$v = 100\% \times \frac{m_q - m_h}{m_q} \tag{1}$$

where m_q = the original mass of gel, g; m_h = the mass of gel in a certain time, g.

2.2.2 *Influence of temperature on foamed gel*

The dehydration rate of material is one of the most important aspects of fire-fighting because the lower dehydration rate the better early stage fire-fighting property. Foamed gel made by 4% of coagulant D, 9% of sodium silicate and 0.2% of foaming agent in preparation for discovering the influence of temperature on it. The foamed gel is set respectively under the stable condition of 20°C, 40°C, 60°C, 80°C, 100°C and 120°C and calculated the dehydration rate during 15 hours by recording its mass per hour.

2.2.3 *The entire dehydration time under different temperature*

The foamed gel containing more than 90% water absorb pretty much heat due to the large specific heat of water. In order to improve the efficiency and persistence of fire-extinguishing such strategies as pouring water in time should be adopted. Put the foamed gel the same material and percentage mentioned above in steel disk whose height is 25 mm while diameter is 150 mm and set stable temperature of drying oven respectively 20°C, 40°C, 60°C, 80°C, 100°C and 120°C then record the six entire dehydration times under different temperature.

2.2.4 *The comparison of thermal stability b between ammonia-free and ordinary gel*

In order to compare the thermal stability in doors for long time, the same foamed gel and ordinary gel mentioned above is put in stable temperature as low as 10°C and their dehydration rate time during 500 hours is calculated per 50 hours. Put the same two materials mentioned above in higher stable temperature of 40°C, 60°C, 80°C and 100°C respectively to calculate their dehydration rate times during 6 hours.

3 RESULTS AND DISCUSSION

3.1 *The selection of coagulant*

Figure.1 shows the comparison of dehydration of foamed gel c and d. Their trend lines are substantially linear and foamed gel d have lower dehydration rate than c in any time where an obvious advantage of coagulant D than C in making foamed gel is shown. In addition, the dehydration rate of foamed gel c is about double of d where can be seen a better fire-fighting persistence in the practical application of the mine. In conclusion, foamed gel made by coagulant D is more appropriate than C.

3.2 *Influence of temperature to foamed gel*

Figure.2 shows the influence of various temperatures ranging from 20°C to 120°C on foamed

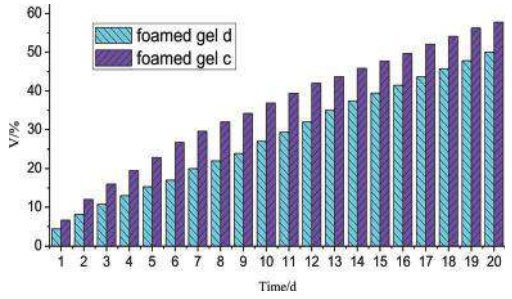

Figure 1. Dehydration rate comparison between foamed gel c and d.

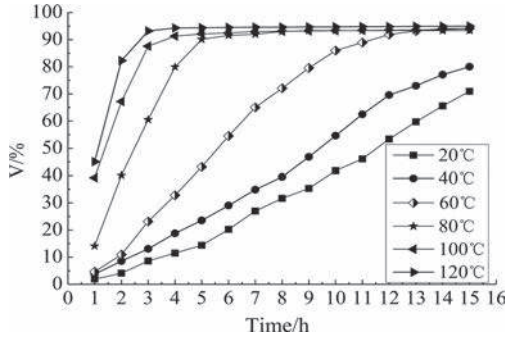

Figure 2. Relationship between dehydration rate of foamed gel d and different temperatures.

gel d. Overall, the dehydration rate of foamed gel increases with increasing temperature. Owing to the larger average energy of the movement of water molecules in high temperature, water -loss rate in high temperature is bigger than that in lower. When the temperature was lower than 60°C, the trend lines of dehydration rate are substantially linear and their own slopes are almost uniform with time; The rate slope is affected by surface control where the surface area is unchangeable when the slope stay invariant and its kinetic equation can be expressed as $v = at + m$. The dehydration rate in 80°C, 100°C and 120°C is bigger than that under 80°C. These three slopes between 0~3 h are almost fixed and is also affected by surface control which fit $v = at + m$; While the lines between 3~6 h are curves and their slopes are affected by diffusion control which fit exponential relationship $v = \alpha \cdot t^{\beta}$ ($\beta < 1$); After 6 hours, their dehydration rates are straight paralleled with x-axis and the slopes are zero when free water vaporize up.

3.3 *The entire dehydration time under different temperature*

As shown in fig. 3, it is concluded that the higher is the temperature, the shorter the complete

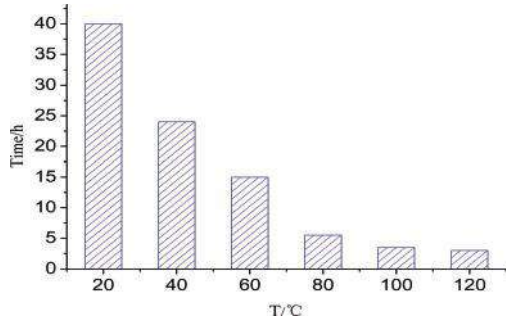

Figure 3. Relationship between complete dehydration time of foamed gel and temperature.

dehydration time. The complete dehydration time above 80°C is much smaller than that below 80°C, and time of 20°C is about ten times than that of 120°C. The main reason of the shorter complete dehydration time is that the steams vaporize fast owing to the accelerated movement of water molecules in high temperature.

The relation between temperature and complete dehydration time is $y = 0.0047x^2 - 1.0198x + 58.2$ with the squared correlation coefficient $R^2 = 0.9959$. Foamed gel filled as fire-fighting material in coal mined-out vaporized gradually, but the loss of water make the effect of absorbing heat and reducing temperature worse. The foamed gel losing some elasticity and strength owing to dehydration also reduces the effect of isolating O_2. The above derived relation may estimate complete dehydration time of foamed gel between 20°C and 120°C. Thus, mined-out will be filled in time to fill mined-out area in time to avoid mine disasters caused by spontaneous combustion.

3.4 *The comparison of thermal stability between ammonia-free and ordinary gel*

To compare the dehydration of foamed gel and ordinary gel for a long time, the dehydration rate of both in 6 hours was compared respectively in the constant temperature, and the condition in 10 °C for 500 hours was observed. The results were shown in figure 4 and figure 5. Results in figure 4 and figure 5 show that dehydration rate of gel is always greater than foamed gel and this trend could remain for a long time. The dehydration rate gap becomes more obvious with time, which proved that foamed gel had better thermal stability than gel under the same conditions. After filling in glue-note area, the free water secreted from gel loses in two ways, which was penetration into the coal seam and evaporation. The dehydration of gel reduced the fire prevention performance. The difference of dehydration measured in experiment is

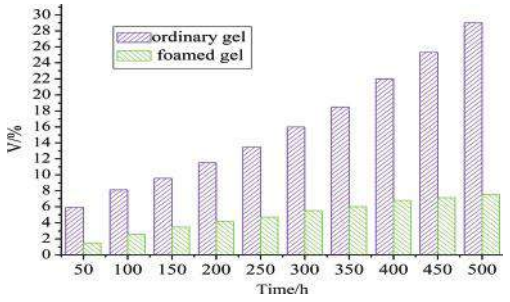

Figure 4. The dehydration rate of ordinary gel and foamed gel at 10°C temperature.

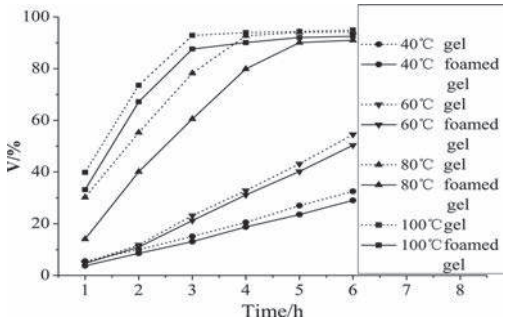

Figure 5. The dehydration rate of ordinary gel and foamed gel at different temperature.

mainly because of the difference in covering performance and physical structure between gel and foamed gel. The structure of the gel is tight and uniform, but foamed gel is different because it is heaped up by foams whose wall is thin and skeleton loose. Those reasons lead to the fact that moisture diffusion in foamed gel is tougher than in gel. And even, the burst of surface foam which then cover over the foamed gel hinder the sublayer foamed gel from water evaporation and diffusion to a certain extent, make the sublayer foamed gel still have plenty of water. For this reason, foamed gel have smaller dehydration rate than gel.

4 CONCLUSION

Foamed gels generated from different coagulants have different states and dehydration rates. Some of these coagulants are appropriate to be gel, but another are not because they are structural soft and collapse easily in mechanical aeration process.

Foamed gel dehydration rate meet different dynamic characteristics in different temperature. When at low temperature process (less than 60°C) and early stage of high temperature process (more than 80°C), the dehydration rate is affected mainly by surface control, fitting the equation $v = at + m$, where the surface area is unchangeable when the slope of curve stay invariant. However, at middle stage of high temperature process, the dehydration rate effected by diffusion, fitting the equation $v = \alpha \cdot t^{\beta}$.

The formula $y = 0.0047x^2 - 1.0198x + 58.2$ is used to describe the relationship between temperature and complete dehydration time of material. Making use of that relation may estimate complete dehydration time of foamed gel between 20°C and 120°C and fill mined-out area in time to avoid mine disasters caused by spontaneous combustion.

Due to lower dehydration rate, which is caused by different covering performance, physical structure and compactness, foamed gel has fire prevention effect in long-term.

The application research of K shortest path algorithm in avoiding mine disaster

F. Wang, H.G. Guo & G.J. Lu
College of Mining Engineering, Taiyuan University of Technology, Taiyuan, China

ABSTRACT: The safety situation of coal mine is still not optimistic in China. The mine disasters seriously affect the safety of life and property of the miners. To avoid the danger, the miners should flee to the safety sites in the shortest time at the beginning of the disaster. Thus, we expound, in this paper, a method to get optimum path in the weighted undirected graph based on the Dijkstra algorithm, and propose a new method of calculating K shortest path. Then combining with mine specific examples, using VB programming language, this paper make it possible to get the two routes quickly and accurately.

1 INTRODUCING THE THEORY OF THE OPTIMAL PATH TO AVOID DISASTER

In recent years, the safety situation of coal mine is relative calm, along with the wide attention from all sectors of society on security issues, especially on the safety of coal mine. However, 1201 accidents have still occurred and killed 1973 people in 2011. The safety situation of coal mine is still not optimistic based on the increasing number of coal mine and the growing coal production. The miners should flee to the ground or underground safe places as soon as possible, to effectively reduce casualties and property losses. In this paper, we focus on helping miners find the optimal path to escape during a fire, thereby they can safely flee in time.

The optimal path to avoid disaster is a route spending the least time from a disaster site to a safe place (Li, 2001). However, the optimal path to avoid disaster might be destroyed, or be no longer suitable to escape, due to the special underground environment, the complicated roadways. Therefore, multiple escape routes will usually be elected in order to nip in the bud, which is the so-called K optimal path to avoid disaster.

1.1 *The calculation method of the optimal path*

Currently, the Dijkstra algorithm is the most authoritative one among many algorithms for the optimal path, due to the easily understanding about the computational process and time complexity. The Dijkstra algorithm is generally used to calculate the optimal path of weighted directed graph. But, both the downwind and upwind roadways can be used as an escape route during the underground escape. Thus, the research of this topic is to find the optimal path of the weighted undirected graph.

The following simply introduces the calculation of the optimal path by the Dijkstra algorithm (Wang, 1994; Ji, 2008):

There is a weighted undirected graph G = (V, E, W), of which V stand for nodes, E stand for edges, and W stand for the weight of every edge. V = {v0, v1, v2, v3…vn}, the set of permanent markers S = {v0}, T = V – S. The parent node of v0 is –1, the parent node of the others is 0. The weight Wij = (v i, v j), if there is no side between vi and vj, then Wij = ∞. Dij is the sum of weight from vi to vj. The initial numerical value of Dij is the same with that of Wij.

The method of calculating the optimal path from v0 to vn is shown as following:

1. For random node, vi ∈ T, D0k = min (D0i), then S = {v0, v k}.
2. For random node, vi ∈ T, if D0k + Wk i < D0i, then D0i = D0k + Wk i, and the parent node of vi becomes vk.
3. After repeating these two steps until vn ∈ S, D0n is the weighted sum of the optimal path.

By seeking the parent node backwards until v0, the optimal path from v0 to vn will be found.

1.2 *The calculation method of the K optimal path*

The traditional method to calculate the K optimal path is defringe algorithm. Specifically, firstly the optimal path is calculated by the Dijkstra algorithm. Then the new optimal path is determined after deleting a random edge of the opti-

mal path. Thus the K optimal path is obtained. This method is relatively complicated, and different optimal paths will be obtained by deleting different edges, resulting in that the k optimal path calculated by this method is not the accurate optimal path, but the approximate shortest path. Based on the traditional Dijkstra algorithm, we proposed a new method to calculate the accurate K optimal path in this paper. The detail is introduced as following:

1. A permanent marking point is made according to the Dijkstra algorithm from the source node also called the positive direction, stored in a collection S. Then the adjacent temporary marker point is modified.
2. A permanent marking point is made according to Dijkstra algorithm from the target node also called the opposite direction, stored in a collection E. Then the adjacent temporary marker point is modified.
3. Another permanent marking point is made from the positive direction, stored in the collection S. The adjacent temporary marking points are then modified. If the permanent tag node is already in the collection E, setting the permanent marker as the center, tracing to find an optimal path respectively according to positive direction and reverse direction. If not, going to the next step.
4. Another permanent marking point is made from the opposite direction, stored in collection E, The adjacent temporary marking points are then modified. If the permanent tag node is already in the collection S, setting the permanent marker as the center, tracing to find an optimal path respectively according to positive direction and reverse direction. If not, going to the next step.
5. Going on one step from the positive direction, one step from the opposite direction, repeat the steps (2) and (3), do the loop continuously, until you find the desires of K, the optimal path or the source node and destination node are all permanent marker, the algorithm is end.

2 INTRODUCTION OF THE SPECIFIC SITUATION OF MINE

With regard to mine system, the intersections of roadways can be considered as nodes, and a roadway can be considered as an edge. Then the complicated roadway relations of mine can be reflected in a network planning. How do we formulate the weight of every side? In fact, the length of each roadway are different, leading to the transit time is varied. Theoretically, the longer the roadway is, the more transit time the roadway needs. Thus, the weight of each side can be represented by the length of corresponding roadway. However, even if two roadways have the same length, the transmit time is different because there are many factors affect the transit time. We can use the influence coefficient to reflect the effect of all factors. Therefore, the equivalent length is obtained by multiplying of the actual length of roadway and various coefficients to reflect the transit time.

Namely, $Wij = Kh * Kw * Kp * Kf * Kv * Lij + \sum Lm$

Of which,

Wij – The equivalent length of roadway;
Kh – The influence coefficient of height of roadway;
Kw – The influence coefficient of width of roadway;
Kp – The influence coefficient of gradient of roadway;
Kf – The influence coefficient of muddy degree of roadway;
Kv – The influence coefficient of wind speed of roadway;
Lij – The physical length of roadway;
n – The number of local obstacles;
Lm – The equivalent length of local obstacles.

3 THE SPECIFIC EXAMPLE

The actual data of ventilation system of one mine in Huasheng are used to determine the K optimal path by combining the parameters of the concrete and VB programming language, in order to guide the escape of mine personnel.

3.1 *The ventilation network map*

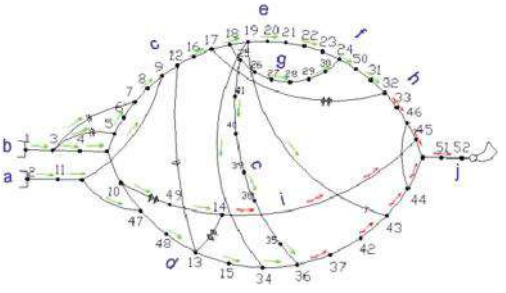

Figure 1. The mine ventilation network diagram of 3101# working face. a, main slope. b, Auxiliary slope. c, auxiliary trading big alley. d, belt transport roadway. e, transportation roadway. f, working face. g, auxiliary transport roadway. h, return airway. i, return air alleys. j, return air shaft.

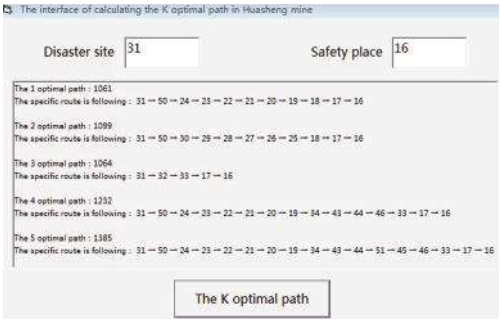

Figure 2. The operation interface.

3.2 *The operation interface of getting the optimal path*

Based on the actual parameters of every roadway, the equivalent length (m) of every roadway can be calculated by the computational formula of equivalent length. Then, the optimal path from any disaster site to the safety place can be obtained by the VB program. The operation interface is showed in Fig. 2.

3.3 *The analyses of the pros and cons of choosing the optimal path*

1. As long as inputting the disaster place and safety place, we can quickly find out the corresponding optimal path and the K optimal path;
2. If the optimal path is broken, we can quickly adjust the escape routes according to the K optimal path;
3. It is the key problem that how to notify the optimal path to disaster personnel timely and accurately. During mine disaster, such as a fire, miners are very panic and difficult to judge the escape direction sanely. So miners should remember expertly the avoiding disaster optimal path. However, during a fire, if the optimal path is changed, we should make use of the communications-equipment to inform miners.

4 CONCLUSION

In this paper, a method of the optimal path in the weighted undirected graph and a new method of calculating the K optimal path are proposed based on the traditional weighted directed graph. The K optimal path is convenient for miner to escape, can also assist in the decision-making of leadership. Further studies should focus on the determination of the changing parameters of the roadway to calculate the optimal path.

ABSTRACT: ZF4403 working face of Xiagou coal mine is the typical thick and spontaneously flammable coal seam fully mechanized caving mining working face under the condition of gas drainage, air leakage in goaf is large, residual coal is thick and coal is broken, the threat of goaf spontaneous combustion is serious during mining face. Combined with the coal seam occurrence condition of ZF4403 working face, seepage model of goaf is established, using the numerical method based on flow field simulation to calculate oxygen concentration and distribution law of air leakage intensity in goaf, and made numerical simulation analysis by Fluent software, combined with the limit parameters of coal spontaneous combustion from experiment, to predict spontaneous combustion dangerous area. The result shows that the reliability of spontaneous combustion prediction simulation data of spontaneously flammable and thick coal seam ZF4403 fully mechanized caving mining working face under the condition of gas drainage is high, boundary values match degree of spontaneous combustion dangerous area is 74.63%~96.78%, width match degree of spontaneous combustion dangerous area is 84.37%~99.78%, simulation data coincided with the measured results on a high level, practicality is good. The range of measured spontaneous combustion dangerous area in goaf where air input is 60.30~174.20 m, the range of that in goaf where air output is 32.60~122.40 m.

1 INSTRUCTIONS

Xiagou coal mine is located in the southern Binchang mining area, easternmost south wing of Dafosi syncline, bordered by Tingkou anticline to the north and Binxian anticline to the south, it is the simple monoclinic structure of north or northwest tilt. Xiagou coal mine is gaseous mine, mainly mining the 4th coal seam, lower Jurassic Yan'an group. The average thickness of the 4th coal seam is 16.80 m, it is low metamorphic humic bituminous coal. 404 mining area is gas abnormal zone, the spontaneous combustion period of 4th coal seam tested by Xi'an University of Science and Technology is 33d, and coal dust is explosive. The fully mechanized mining of spontaneously flammable and thick coal seam under the condition of gas drainage further increased the air leakage in goaf, expanded the scope of spontaneous combustion dangerous area in goaf, increased oxygen concentration in goaf, seepage intensity increased, the oxidation complex reaction time of residual coal and oxygen became longer, greatly improved the possibility of coal spontaneous combustion in goaf. Taking ZF4403 fully mechanized caving mining working face in 404 mining area as an example, seepage model of goaf is established, using the numerical method based on flow field simulation to calculate oxygen concentration and distribution law of air leakage intensity in goaf, and made numerical simulation analysis by FLUENT software, combined with the limit parameters of coal spontaneous combustion from experiment, to predict spontaneous combustion dangerous area. It is greatly significant for building the spontaneous combustion prediction system in goaf of thick and spontaneously flammable coal seam under the condition of gas drainage.

2 PROFILE OF ZF4403 WORKING FACE

The elevation of ZF4403 working face is between +465.35 and +469.28 m, the depth is about 439.70~590.00 m, the upper surface is plateau beam topography cutting by valleys. ZF4403 working face used top coal fully mechanized caving mining technology, roof managed with all caving method. The mining height of working face is 3.10 m, with caving height of 9.30 m and caving ratio 1:3. The strike length of working face is 1800 m, tilt length is 186 m, mining area is 316200 $m^{2,}$ geological reserves is 7.7 million tons, recoverable reserves is 5.37 million tons, recovery rate of 80%, producing 210, 000 tons per month, mineable period is 20.5 months. The geological structure of working face is simple, joints and cracks of coal seam is developed. When driving two lanes and cut, the phenomenon of floor and roof watering gushing locally emerged, mainly for coal seam fracture water. Working face arranged 3 roadways in 4th coal seam, are respectively air return tank, transport trough and draining lane, the average angle of working face is 3°. The air return side is equipped with gas drainage system for goaf gas drainage, spontaneous combustion of residual coal is a very serious problem in the production process.

3 THE INFLUENCE OF GAS DRAINAGE ON COAL SPONTANEOUS COMBUSTION IN ZF4403 GOAF

3.1 *The influence of gas drainage in goaf on air leakage*

The relationship between gas drainage and air leakage in goaf is mainly affected by two aspects (Xu 2002), one is the size of drainage flow; second is the drainage location. Due to the relatively high gas content in ZF4403 working face, a lane of 3.80 m wide and 2.70 m high is arranged as gas drainage tunnel in the coal seam which is 7 m from the roof in the upper part of air return side. The drainage flow is about 444 m3/min, gas concentration from 0.80 to 2.64% with an average of 1.25%. For this high gas drainage roadway that drainage mouth is in close proximity with working face, when drainage flow is less than a critical value, the air leakage of working face gradually reduced with the increase of drainage flow, and turned to increase when the drainage flow exceeded a certain value. When the case of a large flow of gas drainage or diversion of gas, the degree of spontaneous combustion hazard is high. Specific performance is one thing to make spontaneous combustion in the spontaneous combustion dangerous area of original air inlet side intensified, the other is easy to lead local secondary fire area near the mouth of drainage.

3.2 *The dilution effect of gas drainage in goaf on the oxygen concentration in air flow*

The greater the intensity of gas drainage in goaf is, the more the amount of gas emission is, and with the conduct of drainage, the coal gas emission ability becomes greater. Therefore, the gas emission in goaf under the condition of drainage has a dilution effect on the oxygen concentration in goaf. The reduction and uneven distribution of oxygen concentration in goaf is not entirely due to the oxidized consumption of residual coal. Gas distribution and oxygen distribution in goaf is interactive, with the increasing of gas emission intensity, the oxygen gradient becomes greater. From the comparison of air leakage intensity distribution and gas emission intensity in goaf, near the working face, air leakage intensity within the region of goaf is very great, gas concentration is very low, and the impact of gas emission intensity is weak; While in the deep part of goaf, relying on the effect of wind pressure differential across the working face, air leakage from the working face to goaf is extremely weak, and the impact of gas emission is relatively strong.

4 THE MATHEMATICAL MODEL OF LEAKAGE FLOW FIELD IN FULLY MECHANIZED CAVING GOAF

4.1 *The seepage model of goaf*

Fully mechanized caving goaf can be seen as composition of rock and loose coal, As the uneven spatial and temporal distribution of loose coal voids, air leakage source and sink is difficult to determine, leakage flow field is very complex, only considering the average leakage intensity, that is, air leakage through unit area of loose coal. Assuming that the density of air leakage flow in goaf is constant, air adsorption and desorption of loose coal under ambient temperature and pressure achieves balance; then comes to the following balance equation:

$$\frac{\partial \overline{Q_x}}{\partial x} + \frac{\partial \overline{Q_y}}{\partial y} + \frac{\partial \overline{Q_z}}{\partial z} = 0 \tag{1}$$

In the equation, x, y, z respectively represent axis; indicates air leakage intensity (air leakage through unit area of coal).

The gap channel of loose coal in goaf is very irregular, so the staggered and zigzag flow channel makes air flow in loose coal very complex. Statistics

show that even though seepage state in goaf will change in different locations, as the seepage rate in goaf decreases rapidly, goaf seepage state is seen as laminar flow, the seepage momentum equation obeys Darcy's law. It can elicit the goaf seepage model formula (Deng et al. 2004):

$$\frac{\partial}{\partial x}\left(K_x\frac{\partial H}{\partial x}\right)+\frac{\partial}{\partial y}\left(K_y\frac{\partial H}{\partial y}\right)+\frac{\partial}{\partial z}\left(K_z\frac{\partial H}{\partial z}\right)=0 \quad (2)$$

In the formula, x, y, z respectively represent axis; H is total head, Pa; K represents Porous medium permeability coefficient in goaf, Kx = Ky = Kz, According to scene observations and experiments, it can be obtained by the law of permeability influence function of coal spontaneous combustion: voidage f is 0.37, $K = 2.17 \times 10^{-3}$ m^3 · s/kg.

4.2 *Oxygen and gas concentration field model*

The moving process of oxygen in porous media includes diffusion, seepage and mass transfer. Oxygen and gas seepage velocity of loose coal in goaf is generally small, it is seen as laminar flow state. According to the theory of porous mass transfer, the oxygen and gas mass balance equations in loose coal as follow (Deng et al. 2001, Qin et al 2003):

$$\begin{aligned}&\overline{Q}_x\frac{\partial C}{\partial x}+\overline{Q}_y\frac{\partial C}{\partial y}+\overline{Q}_z\frac{\partial C}{\partial z}\\&=D_x\frac{\partial^2 C}{\partial x^2}+D_y\frac{\partial^2 C}{\partial y^2}+D_z\frac{\partial^2 C}{\partial z^2}-V(T)\end{aligned} \quad (3)$$

$$\begin{aligned}&\overline{Q}_x\frac{\partial\left(C_{CH_4}\right)}{\partial x}+\overline{Q}_x\frac{\partial\left(C_{CH_4}\right)}{\partial y}+\overline{Q}_z\frac{\partial\left(C_{CH_4}\right)}{\partial z}\\&=D_{CH_4}\left(\frac{\partial^2 C_{CH_4}}{\partial x^2}+\frac{\partial^2 C_{CH_4}}{\partial y^2}+\frac{\partial^2 C_{CH_4}}{\partial z^2}\right)+S_{CH_4}\end{aligned} \quad (4)$$

In the equations, D represents diffusion coefficient of oxygen in loose coal, it equals to 2.88×10^{-5} m^2/s; V(T) is the oxygen consumption rate of coal in oxygen concentration of C; according to the experiment results, the oxygen consumption rate of Xiagou coal mine 4403 fully mechanized caving mining working face in fresh air flow and under 25°C, it equals to 6.05×10^{11} mol · cm^{-3} · s^{-1}.

4.3 *Definite conditions and boundary conditions*

4.3.1 *Definite conditions*

Assuming that working face pressure is stability, goaf temperature is stability, it is seen as steady-state seepage flow. Namely:

$$\frac{dC}{d\tau}=0 \quad (5)$$

Goaf wall is adiabatic surface. Namely:

$$\overline{Q}=0 \quad (6)$$

4.3.2 *Boundary conditions*

According to the observation data of Xiagou coal mine ZF4403 fully mechanized caving face, comes to the function of oxygen concentration mass fraction of goaf changing with the working surface distance:

Fitting equation of oxygen concentration in air inlet side:

$$C = 0.0000001y^4 - 0.00005y^3 - 0.0024y^2 + 0.0981y + 17.674$$

Fitting equation of oxygen concentration in air return side:

$$C = 0.0000005y^4 - 0.0001y^3 + 0.0124y^2 - 0.4851y + 23.761$$

According to scene observations and experiments, calculated the oxygen consumption rate of Xiagou coal mine 4th loose coal under the oxygen concentration of 21% to be 1.95×10^{-6} kg × m^{-3} · s^{-1}, production rate of CH_4 to be 6.83×10^{-7} kg · m^{-3} · s^{-1}.

5 NUMERICAL SIMULATION OF AIR LEAKAGE FLOW FIELD OF ZF4403 FULLY MECHANIZED CAVING GOAF

5.1 *Physical model of goaf and meshing*

According to the coal seam occurrence and mining conditions of ZF4403 fully mechanized caving face, combining with the dynamic effects of gas drainage system in return corner on goaf spontaneous combustion, using Fluent software, the physical model of ZF4403 fully mechanized caving goaf is established. The model is hexahedron, the length of goaf floor and working face is 195 m, in the places that 200 m deep in goaf, 15 m high to the floor, the energy exchange of wall with the outside world is zero. The thickness of central float coal is 1.77 m, the thickness of float coal in two roadways is 8.86 m.

Taking the intersection of goaf air inlet side and working face as the dynamic origin, the direction to the air return side is x-axis, the direction perpendicular to working face deep into the goaf is y-axis, the direction vertically upwards is z-axis. The mesh step in x-axis and y-axis is 1 m, the grid step of z-axis on the float coal and overburden is 0.20 m. As shown in Figure 1:

Table 1. The quantitative datum of oxygen concentrations simulation in goaf (%).

Depth (m)	18.10	33.10	48.90	64.20	80.50	94.50	107.10	120.60	126.90
Air input side (%)	20.96	20.03	17.74	17.48	17.02	16.45	15.46	13.88	9.87
Air output side (%)	20.97	18.44	16.46	16.33	16.17	10.08	7.45	4.99	4.18

5.2 *Simulation results and analysis*

5.2.1 *Oxygen concentration and gas concentration*

Spontaneous combustion easily happens in the place that oxygen concentration range of 5% to 18%, it is called the spontaneous combustion oxidation heating zone. It can be seen from Figure 2, the 40 m to 180 m deep part of ZF4403 caving face is spontaneous combustion oxidation heating zone. The quantitative datum of oxygen con-centrations of two roadways in goaf calculated by Fluent simulation results is shown in Table 1:

Figure 3 is the gas concentration distribution of the place that is 1 m high to the floor in goaf under the condition of gas drainage. It can be seen from the figure that gas concentration of air return side is higher than that of air inlet side, and converged near the mouth of gas drainage. The gas concentration of two sides both increased with a certain gradient to the deep goaf, in line with the seepage law of goaf. The gas drainage system of air return side makes gas pumped out of goaf, but not enough to pump out all the gas in the deep goaf; it occurs gas accumulation in the deep goaf, but it doesn't pose a threat to working face due to its low oxygen concentration.

5.2.2 *Goaf seepage and relative pressure*

Figure 4 shows the seepage diagram of the place that is 1 m above the floor in goaf. The figure shows the influence of gas drainage system in air return side on goaf seepage. According to Fluent simulation results, The quantitative datum of seepage velocity of two roadways in goaf calculated by Fluent simulation results is shown in Table 2:

Figure 5 is the goaf relative pressure distribution diagram calculated by airflow velocity of air return roadway and air inlet roadway, it can be seen from figure that pressure of goaf air inlet side is larger than air return side for about 20 Pa.

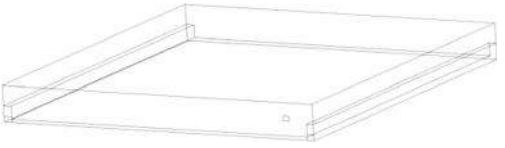

Figure 1. Physical model of ZF4403 mechanized caving goaf.

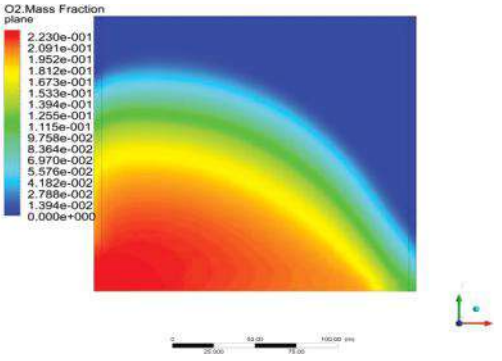

Figure 2. Goaf oxygen concentration distribution.

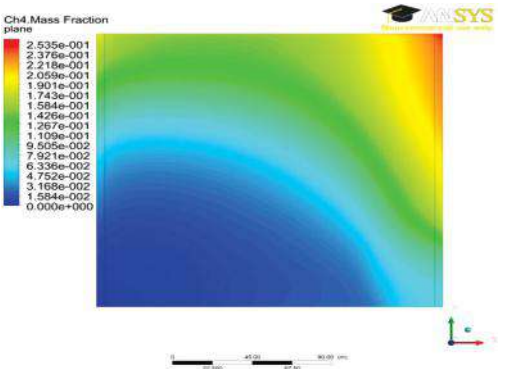

Figure 3. Goaf gas concentration distribution.

6 GOAF DANGEROUS AREA FORECAST AND MATCH DEGREE ANALYSIS

According to the literature, goaf float coal is prone to spontaneous combustion in oxygen concentration of 5% to 18% (Luo et al. 2002, Wang 2005). Numerical simulation results based on Fluent software can be used to calculate the distribution range of spontaneous combustion dangerous area of ZF4403 fully mechanized caving goaf. The measured datum are shown in Table 3, the distribution range of spontaneous combustion dangerous area and match degree analysis are shown in Table 4.

It can be seen from the datum of Table 3 and Table 4 that the width match degree of spontaneous

combustion dangerous area based on Fluent is 84.37% ~ 99.78%; Among the four threshold values of air inlet and return side in goaf spontaneous combustion dangerous area range, except the match degree of cooling zone and oxidation heating zone boundaries with a low degree of 74.63%, the rest are more than 90%. The gas drainage flow in drainage roadway is large, air leakage of inlet side in goaf increases and the distribution gradient of oxygen concentration reduces. Minimum oxygen concentration gradient appears near the working face, the gradient increases towards the goaf direction. It leads to an increasing error of cooling zone and oxidation heating zone boundaries under the condition of a certain error range of oxygen concentration. In summary, the accuracy of Fluent numerical simulation results for forecasting goaf spontaneous combustion dangerous area of Xiagou coal mine ZF4403 working face is worthy of recognition.

7 CONCLUSION

Chose Xiagou coal mine ZF4403 fully mechanized caving mining working face in 404 mining area to research, seepage model of goaf is established, using the numerical method based on flow field simulation to calculate oxygen concentration and distribution law of air leakage intensity in goaf, and made numerical simulation analysis by FLUENT software, combined with the limit parameters of coal spontaneous combustion from experiment, to predict spontaneous combustion dangerous area, come to the following conclusions:

1. Air leakage distribution in goaf is complex under the condition of gas drainage. Air leakage of air inlet side is the largest, air leakage of gas drainage mouth and return air corner comes second. Air leakage in middle goaf reduces with a certain gradient from air inlet side to air return side, the spontaneous combustion range

Table 4. The distribution range of spontaneous combustion dangerous area and match degree analysis.

Division method		Distribution range of spontaneous combustion dangerous area (m)	Width of spontaneous combustion dangerous area (m)
Numerical simulation results	Air output side (%)	30.00~120.00	90.00
	Air input side (%)	45.00~180.00	135.00
Measured results	Air output side (%)	32.60~122.40	89.80
	Air input side (%)	60.30~174.20	113.90
Match degree (%)	Air output side (%)	92.02/98.04	99.78
	Air input side (%)	74.63/96.78	84.37

of middle float coal and air leakage distribution decreases linearly.

2. The goaf gas converged near the mouth of gas drainage, the gas concentration of two sides both increased with a certain gradient to the deep goaf. It occurs gas accumulation in the deep goaf, especially in the deep goaf of air return side, and it is not enough to pump out all the goaf gas, but it doesn't pose a threat to working face due to its low oxygen concentration.
3. The numerical simulation analysis made by Fluent software shows that, boundary values match degree of spontaneous combustion dangerous area is 74.63% ~ 96.78%, width match degree of spontaneous combustion dangerous area degree is 84.37% ~ 99.78%, simulation data coincided with the measured results on a high level, practicality is good. The range of measured spontaneous combustion dangerous area in goaf where air input is 60.30 ~ 174.20 m, the range of that in goaf where air output is 32.60 ~ 122.40 m.

A study of GM (1, 1) residual correction model in gas concentration prediction of heading face

Bing Wu, Zhanyu Liu, Yao Zhou & Peng Lou
Faculty of Resources and Safety Engineering, China University of Mining and Technology (Beijing), Beijing, China

ABSTRACT: In order to fully utilize the existing monitoring data to predict gas emission in coal mine so as to early-warn the gas overrun and guide gas controlling, a mathematical forecasting model is established for dynamically predicting the gas concentration. As the change of gas concentration in coal mine heading face is subjected to many uncertain factors, it is difficult to determine the variation rule of gas concentration. Therefore, the gray theory is used to establish the corresponding dynamic prediction analysis model of gas concentration in which the model modifies the original GM (1, 1) prediction model by using ARMA residual error predictive model, then a modified GM (1, 1) model is established. The modified GM (1, 1) model is applied to gas prediction in the 15, 101 heading face of Xinshun mine. It turns out that the results of gas concentration prediction based on GM residual correction model coincide well with the actual situation. Compared with the situation in which only GM (1, 1) model is used, the prediction accuracy has been greatly improved.

1 INTRODUCTION

Currently, coal mine gas monitoring system is merely used in concentration monitoring and alarm limit, and gas concentration alarm is only about evaluation of the current state rather than possible futural early warning of hazardous conditions. Since the simple real-time data monitoring has been unable to meet modern coal mining on the monitoring requirements, it plays an important role in preventing the gas overrun and guiding gas controlling to learn about how to make full use of existing monitoring data for gas forecast (Wang, 2010, Yan, 2012).

In terms of gas concentration prediction, Zhou Changchun et al. (Zhou & Huang, 1995) have established a fuzzy time series forecasting model to achieve a gas concentration of long-term full-state forecasting; Zhu Yu (Zhu, 2010)have constructed a gas prediction model by using structural neural network learning method; Dong Dingwen et al. (Dong et al., 2011) have achieved gas concentration prediction by using the HHT method to get the instantaneous characteristics of gas concentration time series and combining with three kinds of forecasting model such as autoregressive (AR), radial neural networks and support vector machine; Li gang (Li, 2009) improved the traditional chaotic forecasting methodand put forward the improved algorithm of gas concentration of chaotic time series prediction; TaoYunji (Tao, 2007) have used the improved grey markov model to forecast the gas concentration in working face of stope.

Because of many factors influencing coal mine gas emission (Guo et al., 2009, He et al., 2008, Zhu et al., 2007), such as natural factors (including geological structure, coal thickness, coal structure, buried depth, etc.), mining technology and various combination of factors, it is difficult to determine relationship of factors which are often of non-linear characteristics.

Therefore, coal mine gas emission is a typical grey system (Tao et al., 2007, Wu et al., 2005); gray prediction model can be used to predict the gas concentration.

2 ANALYSIS OF PREDICTION MODEL

The grey system theory is created by a Chinese scholar professor Deng Julong (Deng, 2002), it treats the "small sample, poor information" uncertainty system of "part of the information is known, some information is unknown "as the research object (Deng, 1987). The basic guiding principle of grey prediction GM (1, 1) is transfering the ruleless original data sequence to new regular data sequence through the successive accumulation, weakening the original sequence randomness and on the basis of the new data sequence using the

exponential function curve to get approximation. The advantage is that the modeling process is simple with less sample data and simpler calculation.

Because the gray prediction is a "small sample" prediction based on GM (1, 1) model, and the solution for the GM (1, 1) model is exponential curve, too many sample data lead to a poor accuracy, gas concentration is greatly influenced by mining activity. With the changes of mining and underground environment, old data are gradually diminished and new data's significance will gradually increase, therefore, to make use of gas monitoring data for real-time forecasting of gas concentration, metabolic gray prediction model needs establishing which continuously adds in new data at the same time removing old data to predict the gas concentration (Wei, 2012).

Different ways of prediction would provide us with different useful information, different accuracy of prediction as well (Bates & Granger, 1969, Holden & Peel, 1989, Liu, 2005). Sometimes, to make use of the advantage of each prediction model, different ways are combined to form a prediction group to upgrade the accuracy. There is a relatively big inaccuracy of data prediction in gray prediction model, so we often correct the residual error to improve the accuracy of GM (1, 1) model. In gray theory, setting a GM (1, 1) model with residual error and correcting the original model is used as a way of correcting error (Liu, 2010), however, this method would result in losing information and then influencing the accuracy. Therefore, ARIMA model is needed to be added in grey theory.

3 ESTABLISH OF CORRECTED MODEL BASED ON GM (1, 1) RESIDUAL ERROR

3.1 *Metabolic gray prediction model*

Step one, to select former 10 data from original data:

$$x^{(0)} = \left\{x^{(0)}(1), x^{(0)}(2), ..., x^{(0)}(10)\right\} \tag{1}$$

Since the original data are more likely to be random and irregular, we shall adduct in the whole data and predict with new data array (while 10 data are all constant, the prediction number would be a constant, no need using the below format).

Step two, to smooth the original data with natural logarithm:

$$x^{(0)}(t) = \log(y(t)), t = 1,2,...,10; \tag{2}$$

Step three, adduct in the processed data:

$$x^{(1)} = \left\{x^{(1)}(1), x^{(1)}(2), ..., x^{(1)}(10)\right\} \tag{3}$$

Among them,

$$x^{(1)}(t) = \sum_{i=1}^{t} x^{(0)}(i), t = 1,2,...,10 \tag{4}$$

Step four, to design an accumulation matrix B and constant vector:

$$B = \begin{bmatrix} -\frac{1}{2}(x^{(1)}(1) + x^{(1)}(2)) & 1 \\ -\frac{1}{2}(x^{(1)}(2) + x^{(1)}(3)) & 1 \\ \cdots & \cdots \\ -\frac{1}{2}(x^{(1)}(N-1) + x^{(1)}(10)) & 1 \end{bmatrix} \tag{5}$$

$$Y_N = \left[x_1^{(0)}(1), x_1^{(0)}(2), ..., x_1^{(0)}(10)\right]^T \tag{6}$$

Step five, use method of least squares to solve gray parameter $\hat{a}$:

$$\hat{a} = \begin{bmatrix} a \\ u \end{bmatrix} = (B^T B)^{-1} B^T Y_{10} \tag{7}$$

Step six, to compute the fitting sequence of clustering sequence $\left\{\hat{X}^{(1)}(t)\right\}, t = 1,2,...,10$ and then compute the first-step prediction value.

Step seven, return the fitting model of accumulation sequence to fitting sequence of transformed data sequence $\left\{\hat{x}^{(0)}(t)\right\}, t = 1,2,...,10$ and calculate the latter four values.

Step eight, replace the first data of $y(t)$ sequence with the newly produced data in metabolic way and repeat from step one to eight, and fitting sequence of GM (1, 1) is solved.

3.2 *Residual error correcting model*

ARIMA model is used to correct GM (1, 1) model in order to improve accuracy. In the meantime of verifying the prediction with historical data, we also obtain an error sequence between true values and prediction, and regard it as a random sequence to establish its prediction model, and then correct the GM (1, 1) model with it. The process of establishing ARIMA model is: test the smoothness of residual error, if it is smooth, then establish ARIMA model; if not, smooth it after several times of difference operation and then establish ARIMA model.

After being modified, the GM (1, 1) model is accurate enough to predict the change of gas concentration in 15 minutes, and the error becomes bigger along with the prediction time.

4 MINING FACE APPLICATION EXAMPLE

Xinshun mine is a high-gas one with absolute gas emission of 13.941 m3/min and relative emission of 33.669 m3/t, designed production of 1.8 million t/a as well. As the low permeability of coal seam leads to poor gas pre-drainage efficiency, gas concentration is higher at coal lane tunneling and frequently exceeds the limits. When tunneling stopped, the concentration decreased quickly due to the large gas attenuation coefficient (borehole gas flow attenuation coefficient is 0.1393d-1).

4.1 *Establishment of the gas concentration predict-ion*

The gas concentration monitoring data is selected for analysis which is from 10: 00 to 11:57 on March 2, 2012 in the return air duct heading face, as is shown in Table 1.

GM (1, 1) of grey prediction model is used to fit the above 35 data, the last 5 data for prediction and verifying the forecast results, the results are shown in Table 2.

By comparing the predictive values with the true values, it turns out that simply using GM model prediction leads to large gas concentration error(as shown in table 3).

4.2 *The residual modification of GM model by ARIMA*

4.2.1 *Stationary test of the residual sequence*

Before modeling on the residual sequence, use Eviews6.0 software to check whether the residual sequence is smooth or not, if so, directly establish ARMA model, if not, it has to be taken some steps of difference. After it's smooth, use the ARMA model and establish ARIMA model. Residual sequence is tested on the unit root test, the results are shown in Figure 1:

The Figure 1 shows that the values of t-statistic are less than the critical values of significance level, it means sequence is smooth. So do not use the difference, but ARMA sequence fitting. Consider to use ARMA model, Select the ARMA (2, 2) model as a predictive model. Parameter estimation results are shown in Table 4.

4.2.2 *To test the established model*

The above established ARIMA (2, 0, 2) model is used to fit residual error sequence and obtain the residual sequence of residuals, and its autocorre-

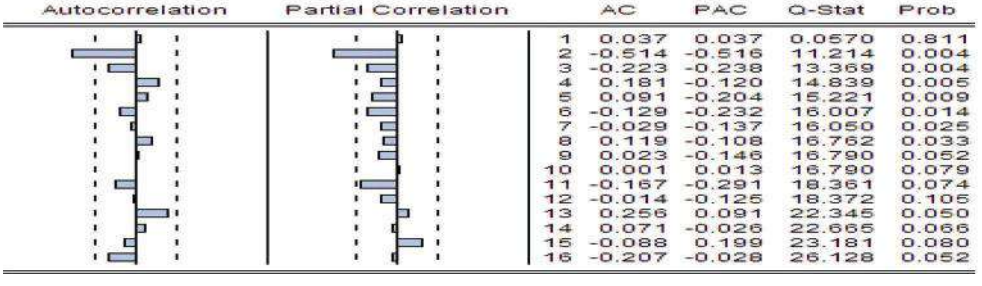
Figure 1. The unit root test of residuals.

4.2.3 *Prediction and error*

The gas concentration for five steps in metabolic GM (1, 1) model and the residuals in the ARIMA model of the residual sequence are predicted and the final prediction and error is shown in Table 5:

Comparing the relative error in Table 5 with Table 3, it can be seen that the corrected model has narrowed prediction errors of simply using GM (1, 1). Therefore, using the ARIMA model residuals modeling program for secondary modeling, re-correcting the main model has a good effect for forecasting the gas concentration change trend. But if mine technician discover abnormal gas emission and artificially take measures to control the gas concentration, it will lead to a decline in gas concentration prediction accuracy.

5 CONCLUSION



GM (1, 1) model based on ARIMA residual error correction is established and the combined model takes advantages of the two kinds of mathematical model, gray forecast model and ARIMA model. Compared with simply using the grey forecasting model, it could improve the prediction accuracy of gas concentration and reduce the relative prediction error.

By adopting the metabolism model (that is, the prediction model automatically weeds out the

old data and makes use of the new data) on the dynamic prediction of gas concentration, we can alarm the gas overrun in advance.

Through the practical application it is concluded that the model can effectively predict the change of gas concentration within 15 min (every 3 min a measurement data), however, in a longer period the predicted results are of large errors.

Study on barrier door of gas explosion with foam ceramics as the main body

Jian-Hua Sun, Zheng Qu, Hong-Yu Fan & Chun-Rong Wei
Heilongjiang University of Science and Technology, Harbin, Heilongjiang, China

ABSTRACT: Based on the studying on barrier device of gas explosion, an optimized design scheme of gas explosion barrier door with foam ceramics as the main body is proposed. The author uses ANSYS software and finite element method to simulate and compare the main performances of four typical doors in thickness, such as uniform thickness, thick in the upper and thin in the lower, thin in the upper and thick in the lower, secant circular. Results of simulation reveal that the moistest stability and good withstand voltage in structure dose the secant circular door have, describe optimization in detail and provide a feasible optimization of barrier device of gas explosion.

Keyword: barrier device of gas explosion, foam ceramics, secant circular door, optimization design

1 INTRODUCTION

The safety production is always threatened by the gas explosion in coal mine. Due to the participation of coal dust, gas explosion will be endowed with a new ability called continuity. The first explosion maybe flowed by secondary explosion or repeated explosion, so that the region of disaster and damage will been enlarged greatly. Therefore, It is necessary and urgent to develop an effective barrier device to avoid secondary and repeated gas explosion.

The barrier device of gas explosion mostly used in coal mine of China are water bag and rock powder shed which can be used to separate different regions. Though having achieved certain results over the past, the lag or advance of working time will influence its barrier explosion effect, such as the water tent and the rock powder tent etc. A new design of partition gas explosion barrier door with foam ceramics as the main body is proposed based on the study of Nie Baisheng, He Xueqiu and Zhang Jinfeng—on effect of foam ceramics upon gas explosion flame propagation. The author plan to set several devices in return airway of working face and crossheading between mining areas to barrier or reduce flame and shock waves propagation of gas explosion, so that the range of propagation will be controlled, the damage degree will be reduced, and the secondary or repeated explosion will be avoided.

2 DESIGN OF BARRIER DOOR

The barrier device consist of three layers—porous metal plate and foam ceramics and porous metal plate, which is similar to the sandwich, as the fig 1 shown. The holes in the two porous metal plate have different center and diameter, and each hole facing the polluted air is filled by a hollow metal spheres to avoid mixing of fresh air and polluted air. As fig 2(a) and fig 2(b) shown, the fig 2(a) is the closed barrier door and the other is open.

After gas explosion, shock waves will break the hollow metal spheres outside the first layer of symmetric porous metal material 2 and arrive at internal material. The special structure of the foam ceramics would reduce the pressure from gas explosion and block it, at the same time, decrease temperature of flame and speed of propagation. If the door can not bear the impact, the more barrier doors we need to set. As a result, the shock resistance of the first barrier door should be regarded as the important parameters, and it will be seriously influenced by the shape of barrier door. To find out most stable door, More analyses and researches on different shapes of doors s necessary.

Using ANSYS software and finite element method to simulate and compare the main performances of four typical shapes of doors, such as shapes of doors uniform thickness, thick in the upper and thin in the lower, thin in the upper and thick in the lower, secant circular.

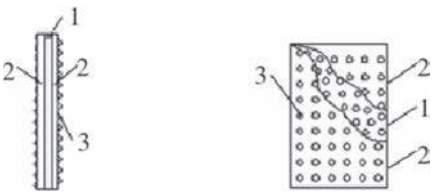

Figure 1. Schematic diagram of material composition of barrier air door of gas explosion (1- ceramic foam, 2- asymmetric porous metal material, 3- asymmetric porous metal material with hollow metal spheres).

3 SIMULATION ANALYSIS OF DIFFERENT MORPHOLOGY OF BARRIER DOOR IN COAL-MINE

The designed barrier door is 200 cm long and 200 cm high and 6 cm thick, and consists of three layers—porous metal plate and foam ceramics and porous metal plate. According to the natural and fixed attribute of material itself, elastic modulus is 72Gpa and Poisson Ratio is 0.226. The elastic modulus and Poisson Ratio of metal plate is 206Gpa and 0.3, which is close to steel.

The optimum item is structural analysis, and element type is Solid, brick 8 node 185.

The first step is to mesh generation;

Displacement constraints: barrier door is fixed by over 5 cm door case and over 30 cm door bank and multi-group high strength hinge, so as to constraint the degrees of freedom of fixed part.

Load constraints: According to the maximum pressure of gas explosion which is 1 to 2 Mpa, the selection of the maximum pressure is 2 Mpa. Using the chosen pressure and constraints on the barrier door to simulate.

After the analysis of ANSYS, the compression situation of four different doors is shown as the fig underside.

3.1 *Uniform thickness*

As the graphs show, the maximum force is 2.35 Mpa on z axis, and the minimum is 1.88 Mpa, the force in the middle of the door and stress in the hinge is larger; the maximum Mises stress is 2.09 Mpa, the minimum is 1.39 Mpa; the maximum displacement on z axis is 0.795×10^{-6} m, the minimum is 0.748×10^{-6} m.

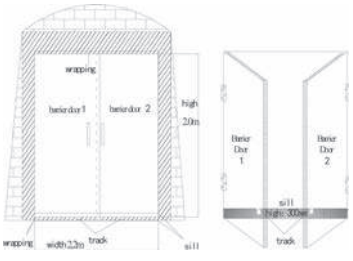

Figure 2. (a) barrier door closed; (b) barrier door open.

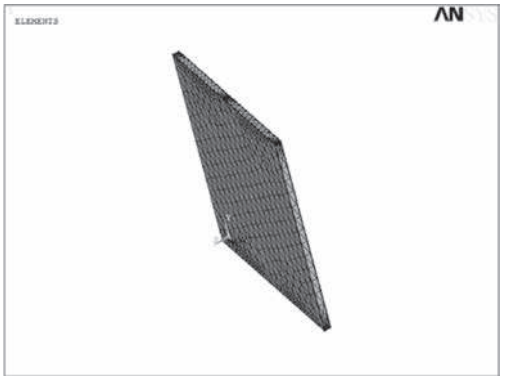

Figure 3. (a) Free mesh generation of uniform thickness.

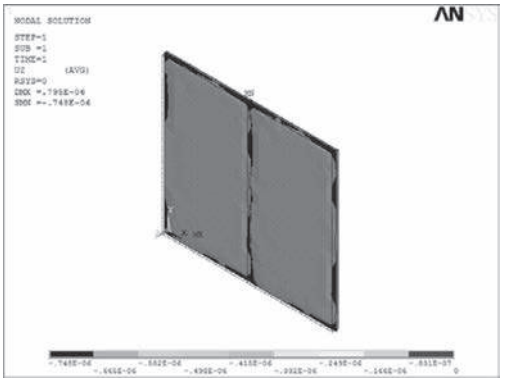

Figure 3. (b) Contour band of displacement on z axis.

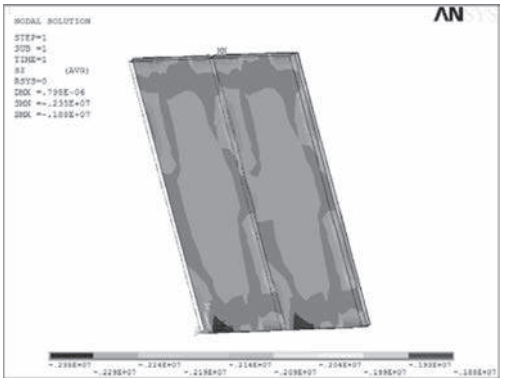

Figure 3. (c) Contour band of force on z axis.

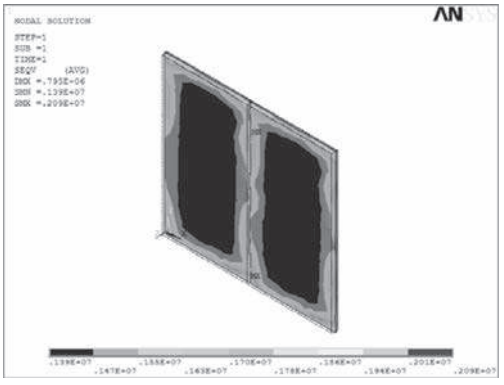

Figure 3. (d) Contour band of Von Mises.

3.2 *Secant circular*

As is shown from the graphs, the maximum force is 5.24Mpa on z axis, and the minimum is 2.77Mpa, the force in the middle of the door is larger than around; the maximum Mises stress is 4.44Mpa, the minimum is 0.687224Mpa; the maximum displacement on z axis is $0.749 \times 10–^{4}$ m, the minimum is 0.301×10^{-5} m.

3.3 *Thick in the upper and thin in the lower*

As the graphs shown, the maximum force is 2.55Mpa on z axis, and the minimum is 1.86Mpa, the force in the upper of the door is larger than around; the maximum Mises stress is 2.25Mpa, the minimum is 1.4Mpa; the maximum displacement on z axis is 0.131×10^{-5} m, the minimum is 0.119×10^{-5} m.

3.4 *Thin in the upper and thick in the lower*

As the graphs show, the maximum force is 2.55Mpa on z axis, and the minimum is 1.86Mpa, the force in the lower of the door is larger than around; the maximum Mises stress is 2.24Mpa, the minimum is 1.4Mpa; the maximum displacement on z axis is 0.131×10^{-5} m, the minimum is 0.119×10^{-5} m m.

4 CONCLUSION

1. The pressure distribution of different foam ceramics on each axis is shown as fig. 7(a), the shock wave pressure spread regularly and change greatly on Z axis; secant circular door can sustain the maximum pressure of 24Mpa, which is 2.5 time than others.
2. As the fig. 7(b) show us, the uniform thickness door, thin in the upper and thick in the lower door and thick in the upper and thin in

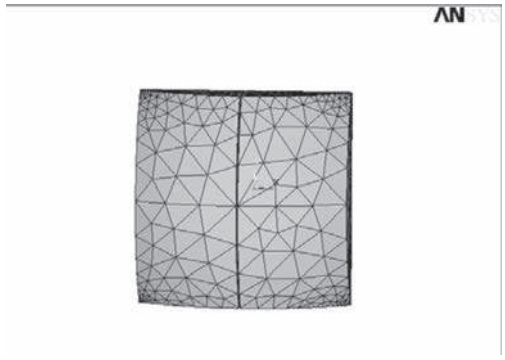

Figure 4. (a). Free mesh generation of uniform thickness.

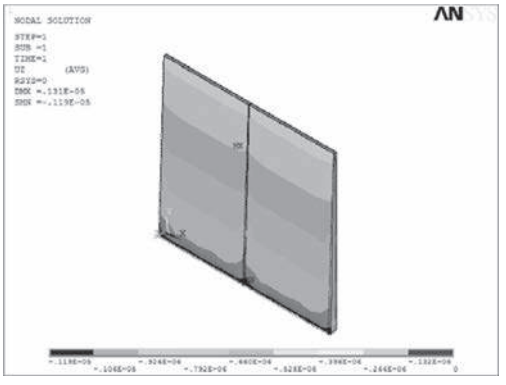

Figure 6. (d) Contour band of Von Mises.

the lower door have the same displacement on X axis dose, thick in the upper and thin in the lower door has less displacement on Y axis dose, uniform thickness door has less displacement on Z axis dose; the maximum displacement

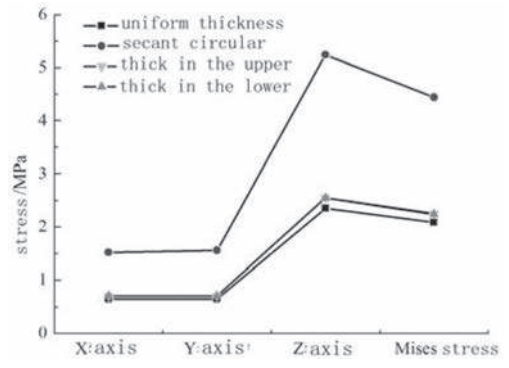

Figure 7. (a) Comparison of axial stress in different form barrier doors.

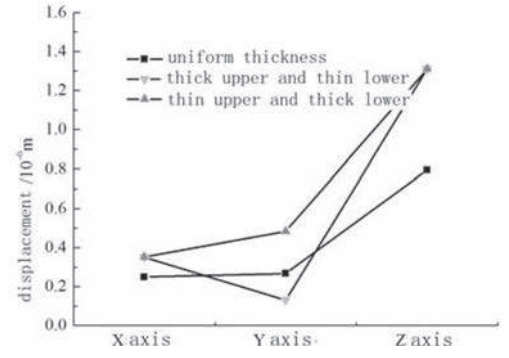

Figure 7. (b) Comparison of displacement in different form barrier doors.

0.108×10^{-3} m which is 30 times higher than the other three, which is not easy to display in the graph, occurred in the simulation of secant circular door; however, the actual displacement is about 1.1 mm. The author believes that the geometry of circle should be considered, and the steadiness of circle results from its distribution under the stress conduction, and the circle can be quickly restored to the original strength after the reversible deformation;

3. The force of secant circular door was shown as vertical band, and the forces in the middle or on the whole device is larger, and the largest force would be found in the middle of the door and docking part; stress concentration always occurs in the geometric center of the door. Strengthening the outer plate and oversizing strength and density of the host materials would solve the problem.
4. The docking part is the thickest part of the door, and the thick dose of door will cause the increasing of blocking probability and sharp increasing of stress. In order to avoid that, the

porosity of this part would be increased, so that shock wave can pass through freely; as a result, sharp increasing of stress would not occur.

Prediction of coal and gas outbursts with random forests

Yong Lin, Xingjia Lu & Jianbo Fan
College of Science, Ningbo University of Technology, Ningbo, Zhejiang, China

ABSTRACT: Coal and gas outbursts are one of the most serious and devastating risk factors accompanying mining industry. In order to reduce the possibility of outbursts, it will be helpful to find out perfectly suitable classification algorithms, for the prediction of coal and gas outbursts. Ensemble classification algorithms predict class label of unknown records by aggregating predictions made by multiple classifiers and they are proved to be robust and precise in supervised learning technology. Based on our experiments, we found that the random forest algorithm demonstrate better performance compared with other ensemble methods, such as Bagging and Boosting. Another, the random forest algorithm is more stable than decision tree classifiers, and the experiments demonstrate that it is a good candidate for the prediction of coal and gas outbursts. We also explore the issue about how to configure a preferable profile for the random forest algorithm for the prediction of the outbursts.

1 INTRODUCTION

Gas is released often during coal mining process when the subsequent pressure release in the surrounding strata. At certain concentrations and volumes, gas may cause major risks of explosions and asphyxiation (Imgrund & Thomas 2013). On certain conditions, gas is released suddenly from coal mine, known as a coal and gas outburst (or gas outburst). This phenomenon has occurred in most coal producing countries and catches attentions from different nations accordingly in the history. With the recent development of the technical and political conditions, coal and gas outbursts only take place in a few countries. A lot of experience gained in the past has disappeared. Today apart from Australia, gas outbursts are a significant problem in China, Kazakhstan, Ukraine, Germany, Turkey and Mexico.

The prediction of coal and gas outbursts becomes a hot topic in recent years. An accurate predictor will be helpful for coal mine to take corresponding policy to reduce the possibility of disasters and save life from dangers. Researchers attempted various approaches, including neural network, grey correlation, SVM, etc. (Wangsheng et al. 2003). Using the neural network approach, the predicted weight sometimes turns out to have unreasonable distribution (Shiliang & Aiyou 2009). By grey correlation, the accuracy of the prediction may become worse unless the training data has a large amount (Hua et al. 2009). Although the SVM algorithm has been applied to the prediction of coal and gas outbursts, an appropriate kernel function needs to be carefully designed and verified. While the machine learning technology provides us a great deal of classification algorithms. In this paper, we focus on the feasibility and usability of decision tree algorithms and ensemble learning (Dietterich 2000) algorithms for the prediction of gas outbursts.

Since we get enough measuring parameters from historical coal and gas outburst events, which can be used as features of the coal mine and gas condition for the outbursts. Then for any other coal mines, it will be naturally to rely on supervised learning to predict the possibility of their future outburst given the historical feature data of outbursts. The ensemble methods have been proved to be very successful supervised learning. Ensembles combine multiple hypotheses to form a better hypothesis. In other words, an ensemble is a technique for combining many weak learners in an attempt to produce a strong learner. The term ensemble is usually reserved for methods that generate multiple hypotheses using the same base learner. The broader term of multiple classifier systems also covers hybridization of hypotheses that are not induced by the same base learner. Evaluating the prediction of an ensemble typically requires more computation than evaluating the prediction of a single model, so ensembles may be thought of as a way to compensate for poor learning algorithms by performing a lot of extra computation. Fast algorithms such as decision trees are commonly used with ensembles and served as random forests, which will be more stable and robust for the prediction.

2 RANDOM FOREST

2.1 *Tree classifiers and ensemble learning*

Tree classifiers are unstable due to unexpected distribution of the real data (Leistner et al. 2009). An ensemble is a supervised learning algorithm, since it is trained first and then used to make predictions. The trained ensemble represents a single hypothesis. Empirically, ensembles tend to yield better results when there is significant diversity among the models (Kuncheva & Whitaker 2003). Therefore, ensemble methods are normally designed to promote diversity among the models in their combination.

Random Forests (RFs) are a combination of the weak classifiers of tree, and this can be used as ensemble to produce a strong learner. Each tree depends on the values of a random vector sampled independently and with the same distribution for all trees in the forest. The generalization error of a forest of tree classifiers depends on the strength of the individual trees in the forest and the correlation between them. Using randomly selected features to split each node will yield error rates that compare favorably to Adaboost, therefore RFs are expected to be more robust with respect to noise (Kotsiantis 2007).

At each internal tree node, a decision forest randomly can select F feature attributes, and evaluate just those attributes to choose the partitioning attribute. They tend to produce trees larger than trees where all attributes are considered for selection at each node, but different classes will be eventually assigned to different leaf nodes. At each internal tree node, RFs evaluate the quality of all possible partitioning attributes, but randomly select one of the F best attributes to label that node based on information gain, etc. RFs are an effective tool in prediction compared with boosting and adaptive bagging.

Bagging alone utilizes the same full set of predictors to determine each split. However the RF algorithm applies another judicious injection of randomness: namely by selecting a random subset of the predictors for each split (Breiman 2001). The number of predictors to try at each split is known as m_{try}. While this becomes new parameter, typically (classification) or (regression) works quite well. RFs are not overly sensitive to m_{try}. While Bagging is a special case of random forest where $m_{try} = k$.

2.2 *Random forest classifier*

A random forest is an ensemble of decision trees. Each tree in the forest is built and tested independently from other trees; hence the overall training and testing procedures can be performed in parallel. During the training, each tree receives a new bootstrapped training set generated from the original training set by subsampling with replacement. We refer to those samples which are not included during the training of a tree as the out-of-bag samples of that tree (Leistner et al. 2009). These samples can be used to compute the out-of-bag-error of the tree as well as for the ensemble which is an unbiased estimate of the generalization error.

During training, each decision node of the tree creates a set of random tests and then selects the best according to quality measurement such as information gain or Gini index. The trees are usually grown to their full size without pruning. We denote the nth tree of the ensemble as

$$f_n(x) = f(x, \theta_n) : \mathrm{X} \rightarrow \mathrm{Y} \tag{1}$$

where θ_n is a random vector capturing the various stochastic elements of the tree (such as the randomly subsample training set or selected random tests at its decision nodes). We denote the entire forest as $F = \{f_1, \ldots, f_N\}$, where N is the number of trees in the forest. We can write the estimated probability for predicting class k for a sample as

$$p(k \mid x) = \frac{1}{N} \sum_{n=1}^{N} p_n(k \mid x) \tag{2}$$

where $p_n(k|x)$ is the estimated density of class labels of the leaf of the nth tree. The final multi-class decision function of the forest is defined as

$$C(x) = \arg\max_{k \in Y} p(k \mid x) \tag{3}$$

Breiman (2001) defined the classification margin of a labeled sample (x, y) as

$$m_l(x, y) = p(y \mid x) - \max_{\substack{k \in Y \\ k \neq y}} p(k \mid x) \tag{4}$$

It is obvious that for a correct classification, $m_l(x,y) > 0$ should hold. Therefore, the generalization error is given by

$$GE = E_{(X,Y)}(m(x, y) < 0) \tag{5}$$

where the expectation is measured over the entire distribution of (x, y), and the error has an upper bound in form of

$$GE \leq \bar{\rho} \frac{1 - s^2}{s^2} \tag{6}$$

where $\bar{\rho}$ is the mean correlation between pairs of trees in the forest 1 and s is the strength of the

ensemble (i.e., the expected value of the margin over the entire distribution).

3 EXPERIMENTS

3.1 *Data preparation*

Experiments are taken to verify the performance of different algorithms for classifying coal and gas outbursts. Four indexes are chosen as features of coal and gas outbursts: drill cuttings analysis index (K_1), the maximum amount of drilling (S), drilling gas inrush initial velocity (q_0), coals solidity coefficient (f) (Xuchao & Dongling 2011, Chenggong & Youan 2004). The experiments are implemented with multiple classes of outbursts, representing outburst tendency (tendency), outburst, and no outburst (normal). We use a set of data from the outbursts of several coal mines in China (Yu-feng & Zhong-cai 2010, Tao & Tianwei 2011). Of the total 40 records, 66% are used for training and others for testing. Table 1 presents some sampling data for the features of coal and gas outbursts.

3.2 *Statistical metrics of predictive results*

The experiments are taken with Weka machine learning package, and the results are evaluated by several statistical metrics. We provide an explanation of these parameters in the following parts. The statistical metrics of the predictive results are evaluated by accuracy, Kappa statistics, mean absolute error, root mean squared error, and relative absolute error. For the prediction performance, we normally refer to accuracy, which is the number of correctly classified instances versus the number of total instances, known as percent agreement calculation. The Kappa statistics, also called Cohen's kappa coefficient (Kappa), is a statistical measure of inter-rater agreement for categorical items (Carletta 1996). It is generally thought to be a more robust parameter than simple percent agreement calculation, since Kappa takes into account the agreement occurring by chance.

Table 1. Features for coal and gas outbursts.

No.	K_1	S	q_0	f	Outburst
1	1.46	2.79	3.29	1.63	Tendency
2	2.18	4.03	4.55	0.29	Outburst
3	1.48	3.10	2.78	1.88	Tendency
4	2.22	4.13	5.11	0.36	Outburst
5	0.57	1.92	4.03	2.27	Tendency
6	1.17	2.03	0.97	2.48	Outburst
7	2.24	1.98	3.21	0.29	Normal
8	2.19	4.38	5.23	0.34	Outburst
9	0.77	2.52	2.34	2.16	Normal
10	2.23	4.31	5.09	0.31	Outburst
11	1.46	2.61	4.15	1.75	Tendency
12	2.21	3.98	4.59	0.35	Outburst
13	0.72	2.35	2.55	2.15	Normal
14	0.68	2.58	2.79	2.43	Normal
15	2.19	4.13	5.22	0.36	Outburst
16	1.40	3.01	4.09	1.75	Tendency
17	0.89	3.45	4.34	2.78	Tendency

$$Kappa = \frac{\Pr(a) - \Pr(e)}{1 - \Pr(e)} \tag{7}$$

where Pr(a) is the relative observed agreement among raters, and Pr(e) is the hypothetical probability of chance agreement, using the observed data to calculate the probabilities of each observer randomly saying each category. If the raters are in complete agreement then $Kappa = 1$. If there is no agreement among the raters other than what would be expected by chance, $Kappa = 0$.

In statistics, the Mean Absolute Error (MAE) is a quantity used to measure how close forecasts or predictions are to the eventual outcomes, which is an average of the absolute errors $e_i = |\hat{x}_i - x_i|$. The mean absolute error is given by

$$MAE = \frac{1}{n}\sum_{i=1}^{n} |\hat{x}_i - x_i| \tag{8}$$

The Root Mean Squared Error (RMSE) of predicted values $\hat{x}_t$ for times t of a regression's dependent variable x_t is computed for n different predictions as the square root of the mean of the squares of the deviations:

$$RMSE = \sqrt{\frac{\sum_{t=1}^{n} (\hat{x}_t - x_t)^2}{n}} \tag{9}$$

Mathematically, the Relative Absolute Error (RAE) of an individual program is evaluated by the equation:

$$RAE = \frac{\sum_{i=1}^{n} |\hat{x}_i - x_i|}{\sum_{i=1}^{n} |x_i - \bar{x}|} \tag{10}$$

where $\bar{x} = \frac{1}{n}\sum_{i=1}^{n} x_i$ is the average value of the samplings.

The Root Relative Squared Error (RRSE) is computed by dividing the RMSE by the RMSE obtained by just predicting the mean of target values (and then multiplying by 100). Therefore, smaller values are better, and the values >100%

indicate that the scheme is doing worse than just predicting the mean. The root relative squared error of an individual program *i* is evaluated by the equation:

$$RRSE = \sqrt{\frac{\sum_{i=1}^{n} (\hat{x}_i - x_i)^2}{\sum_{i=1}^{n} (x_i - \overline{x})^2}} \tag{11}$$

3.3 *Experimental results*

Experiments are taken for random forest and other tree classification algorithms, as well as several ensemble algorithms. For comparison with the tree classification algorithms, we choose several tree like classification algorithms, including Best-First decision Tree (BFTree), decision stump, Functional Tree Algorithm (FT), J48 decision tree-inducing algorithm, Logical Analysis of data Decision tree (LAD), Naive Bayesian decision Tree (NBTree), random tree, Reduced Error Pruning Tree algorithm (REPTree).

For ensemble algorithms, we consider AdaBoost as well as Bagging. The weak classifier for AdaBoost is the DecisionStump algorithm. The experimental results for coal and gas outbursts are given in Table 2.

The results indicate that RF has an accuracy of 85.71%, which is better than BFTree, DecisionStump, FT, J48, LADTree, NBTree, RandomTree, REPTree. Also, compared with the ensemble algorithms of AdaBoost and Bagging, the accuracy of RF is also better for nearly 15%.

For Kappa statistics, the RF algorithm has a value of 0.77, which is higher than all other algorithms. This indicates that the raters have greater chance of agreement than other algorithms. For the Mean Absolute Error (MAE), random forest is also better than other algorithms except for the RF algorithm, which indicates that although the MAE is useful to represent the absolute errors, its value is not enough to represent the quality of prediction yet. While the Root Mean Squared Error (RMSE) provides more precise statistics of the prediction error, and the RMSE value of random forest is lower than other algorithms accordingly. As for the Relative Absolute Error (RAE) and the Root Relative Squared Error (RRSE), the results demonstrate similar performance as for MAE and RMSE. Also, for RRSE, if the values are greater than 100%, it indicates the algorithms are rather worse for the computing. From the results, we can come to a conclusion that the algorithms of BFTree, DecisionStump, FT, J48, LADTree, REPTree are not suitable for the prediction of outburst, at least for the case when we refer to K_1, S, q_0 and f.

Next, we take experiments to verify the performance of different forests for the computing. The number of trees ranges from one to ten, then the time spent for the prediction of coal and gas outbursts changes a little bit from 0.002 seconds to 0.01 seconds (Figure 1), which indicates that the RF algorithm is fast enough for the computing of outbursts in real engineering.

In order to figure out how many trees are suitable for the random forest, we further refer to the statistical parameters. From Figure 2, when there is only 1 tree, the Kapa statistics is 0.65, while it increases to 0.77 when the tree number is 7 or above. The measurement of error also becomes tolerable when the number of trees increases, and as is shown in Table 2, the MAE is 0.21 and the RMSE is 0.31 when the number of trees is 10. Although the RMSE is 0.13 when the number of trees is 1, the MAE has a value of 0.38 and this is higher than the value of other number of trees. These results indicate, if we only refer to the RMSE, we still cannot evaluate the error precisely. While it is similar for the RAE, it is only 33% when the

Table 2. Comparison of Random Forest with Other Algorithms.

Algorithm	Accuracy (%)	Kappa	MAE	RMSE	RAE (%)	RRSE (%)
BFTree	57.14	0.26	0.34	0.48	78.58	102.78
DecisionStump	57.14	0.15	0.38	0.47	88.53	102.10
FT	57.14	0	0.29	0.53	65.91	115.14
J48	57.14	0.26	0.34	0.48	78.58	102.78
LAD Tree	57.14	0.15	0.27	0.48	62.80	104.24
NBTree	71.42	0.46	0.30	0.39	70.11	83.05
RandomTree	78.57	0.66	0.14	0.38	32.95	81.42
REPTree	57.14	0.15	0.38	0.47	88.53	102.10
RandomForest*	85.71	0.77	0.21	0.31	48.33	66.64
Ada Boost	71.43	0.49	0.35	0.39	81.08	84.89
Bagging	64.29	0.44	0.33	0.38	76.14	81.91

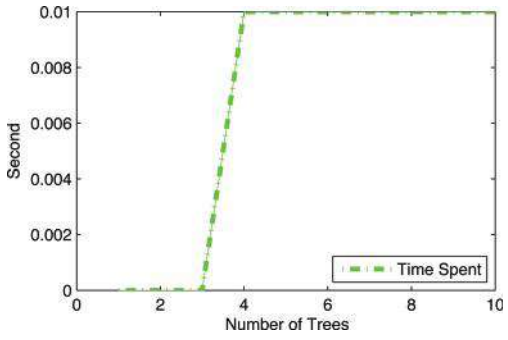

Figure 1. Time spent for the computing of random forests.

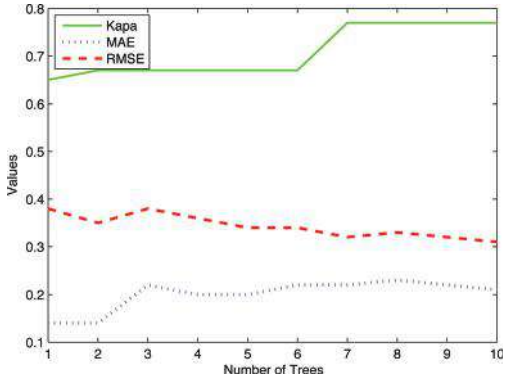

Figure 2. Variation of Kapa Statistics, MAE, RMSE in Random Forests.

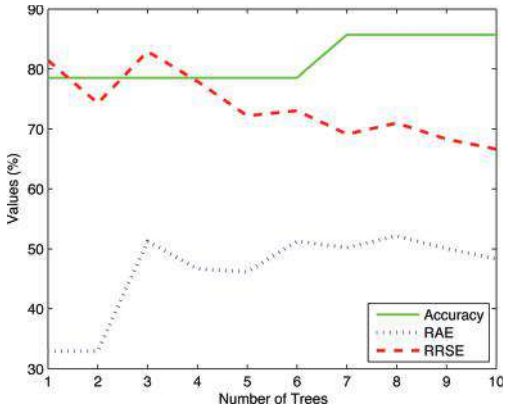

Figure 3. Variation of accuracy, RAE, RRSE in random forests.

number of trees is 1 (Figure 3), much lower than that of other number of trees. But the RRSE is 82% when the number of trees is 1, which means the root relative squared error is rather high. The accuracy for 7–10 number of trees also becomes 82% when the number of trees is 7 or above, and the errors of MAE and RMSE is about 0.35 and 0.2 respectively. Therefore, ideally the number of trees in the RF algorithm will be 7 or above.

4 CONCLUSIONS

Coal and gas outbursts are serious risk factors for the mining industry, but the machine learning technology provides useful methods to predict this phenomenon. By analysis of four parameters from historical outbursts, K_1, S, q_{10}, and f, we evaluate the effectiveness of different machine learning algorithms. We provide a comparison of the decision tree algorithms and ensemble algorithms, and find out that the ensemble decision tree—random forest, demonstrate good performance for the outburst prediction. When the number of trees goes to 7 or above, the prediction accuracy reaches expected level and the error rate is tolerable, which is acceptable for the outburst prediction. Correspondingly, some decision tree algorithms exhibits worse error rate and are not expected to be used directly for the prediction.

Faculty of Engineering and Information Sciences, University of Wollongong, New South Wales, Australia

ABSTRACT: Goaf Frictional Ignition (GFI) poses a serious threat to the safety of underground coal mines, and has caused many underground fires and catastrophic explosions. This paper examined occurrences of GFI incidents and the underlying mechanisms of ignition source and environment. Most of these incidents were attributed to rock on rock frictional ignition. The eventuation of frictional ignition relies on the presence of hot spots with enough incendive ignition energy, which requires a minimum threshold sliding distance and sliding velocity. The incendivity of the environment can be enhanced by the presence of liquid carbon hydrogen, the increase of virgin rock temperature, and the presence of hydrocarbon gases from thermal decomposition product of coal volatile. The paper discussed the newly proposed concerns on the varying incendivity of environment; finally it summarized the GFI engineering controls and discussed their applicability.

1 INTRODUCTION

Goaf Frictional Ignition (GFI) refers to the ignition of flammable gas mixture by friction in the goaf area. It poses great threats to the underground coal mine safety. Goaf fires and explosions emanating from it have caused substantial property losses and casualties all around the world. On July 16th, 1986, 12 people were killed by an explosion in Moura No. 4 Underground Mine in Central Queensland, and GFI was suspected as one of the two possible ignition sources (Lynn et al. 1986). In USA 1997, an explosion occurred in Upper Big Branch underground coal mine and caused considerable property loss, which was surely induced by GFI (Page et al. 2010). A fatal explosion happened in Sago Mine, West Virginia, USA, where 12 men were killed on January 2nd, 2006, and GFI was not ruled out as a possible cause (Gates et al. 2007). In New Zealand, the Pike River coal mine explosion disaster on November 19th 2010 killed 29 out of the total 31 underground workers at that time. As no one has been able to reenter the coal mine after the explosion, the ignition source of the first explosion has not been determined by scene inspection and GFI remains a possible ignition source (Royal Commission on the Pike River Coal Mine Tragedy 2012). The mine geology, mining conditions and the incidents history at Pike River indicate a high possibility of frictional ignition in the goaf; It is a gassy mine, over a five-day period in October 2010 there were six over 5% methane overrun panel; sandstone, which has high incendivity, directly overlies the active coal seam with the thickness of over 30 meters; and the incendivity of the sandstone was substantiated by the frictional ignition incidents in the mine's tunnel development phase; it adopted free-standing goaf management strategy, and the coal extraction height was in 10–13 meters range, which can yield friction velocity from 14 to 16 m/s, and this velocity range has been proven to be readily to cause frictional ignition; The width of the panel was 31 meters, which was capable to yield plate like rock falling, and this has been proven by the platelike roof falling with windblast on 30th October 2010, while the plate-like roof falling blocks can provide friction platform with sufficient sliding distance for the overlain falling rocks (Royal Commission on the Pike River Coal Mine Tragedy 2012).

The incidences of GFI have been reported even more in China. China extracts about half of the world's total coal production, and over 90% of that is from underground coal mines. On 14th February 1999, at Xinjian coal mine Qitaihe city of Heilongjiang Province, methane accumulated in an abandoned conveyor roadway which connected to a high gassy coal seam. The impact and friction associated with the cave-in of the rich quartz sandstone roof ignited the firedamp, and caused an explosion which killed 49 men (Yang & Gu 2010); On 5th November 1999, at Yinan coal mine of Handan City in Hebei Province, methane built-up under the massive free-standing roof in the goaf, the friction and impact during the caving of the roof ignited the firedamp, caused an explo-

sion which killed 33 men (Yang & Gu 2010). At Meiyukou and Xinzhouyao coal mines of Datong Mining Group, goaf methane ignitions have been reported times, and the fires were called 'ghost fires' by underground coal miners. On 3rd December 2005, at 8317 fully mechanized longwall face in Xinzhouyao coal mine, during the goaf roof caving, a stream of flame came out of the goaf, which caused face stop for nearly 1 week. After analyzing and investigating the accident causes, open flame, blasting explosives and electrical charges were ruled out, and rock on rock frictional ignition was considered to be the most possible cause (Yang & Gu 2010). A total of 26 goaf methane explosion (fire) incidents were reported in the counties of Yang Cheng and Qinshui in China. After ruling out the possibilities of open flame, blasting explosive, detonators, electrical arc and contrabands, these incidents were attributed to rock on rock frictional ignition (Qin 2005).

2 MECHANISMS OF GFI

The eventuation of frictional ignition relies on the co-presence of both incendive ignition source and incendive environment. Systematic and comprehensive investigations were conducted on the ignition source, and the corresponding mechanisms were proposed, developed and substantiated by laboratory experiments and field observations. The study on incendivity of ignition environment mainly focused on the methane concentration of methane-air mixture. Some new factors which affect the incendivity of the environment have been identified by researchers and preliminarily probes have been conducted on these concerns. This section critically examines the ignition source mechanisms and their supporting laboratory tests, and distilled the core of research outcomes from the perspective of industrial engineering controls. This section also summarizes the new concerns on the incendivity of the environment and the ongoing research outcomes.

2.1 *Ignition source mechanisms*

From the perspective of ignition sources, frictional ignition can be broadly divided into three categories: rock on rock, metal on rock, metal on metal. As in the goaf area, the presence of metal is rare, so GFI can be classified as the rock on rock, which has been proven to be incendive enough to ignite explosive range methane-air admixture theoretically and experimentally. Insights into the corresponding mechanisms have gone through different phases and gradually matured (Burgess & Wheeler 1928, Nagy & Kawenski 1960, Page 2010, Rowell 1969, Powell & Billinge 2001, Qin 2003, Qin 2005, Rae 1964, Ramsay et al. 1965, Ward et al. 2001, Wynn & Britain 1952).

Although it was the sparks generated from the impacts and friction that raised the concern of frictional ignition, it has been proven that most of the frictional ignitions were not caused by sparks, provided that the sparking particles are not pyrite, which can burn in the air. Burgess and Wheeler from UK SMRE (Safety in Mines Research Establishment) found in the laboratory that it was very difficult to ignite admixtures of methane and air with sparks (Burgess & Wheeler 1929), and Blickensderfer et al. from U.S. Bureau of Mines confirmed the above finding (Blickensderfer et al. 1972). Researchers revealed that methane ignition requires a high temperature (no less than 650 °C) associated with adequate heating area and induction time, while sparks do not usually possess the adequate combination of life time, temperature, and surface area (Trueman 1985). Australian researchers Ward et al. observed the ignitions associated with the presence of sparks, and found that ignitions mostly developed from the contact points of friction rather than sparks (Ward et al. 2001). Pyrite sparking particles are another story, because they can react with oxygen, generate more heat and keep the temperature going higher, and then prolong the lifetime above the incendive temperature (Ward et al. 2001, Allsop 1939). In conclusion, previous research conducted inlaboratory illustrated that normal sparks which just hold the frictional heat are not capable of being the ignition source in most frictional ignition cases.

Hot spots consisting of molten minerals from sliding rocks, which appear at the contact point of sliding rocks and its trail, are the major contributor to frictional ignitions. Hot spots mechanism was firstly proposed in 1929, when Burgess and Wheeler argued that a stationary spark at the contact between cutting pick and the rock might be ignition source, which is equal to the hot spot (Burgess & Wheeler1929). Powell from UK SMRE reported that in a set of rubbing tests with rock sample cube rubbing against sandstone wheel enclosed in a 7% methane-air mixture, when ignitions occurred, the subsequent examination always revealed patches of glassy, fused quartz on the rubbed surface of the rock sample cube, which were the chilled hot spots (Powell & Billinge 1975). The high-speed cine-film, which recorded on another set of tests, also confirmed the presence of hot spots at the friction trace (Powell & Billinge 1975, Powell et al. 1975). Ward et al. observed the frictional ignitions in his tests, and found that ignitions originated from the hot spots at the close trail of the contact point of friction (Ward et al. 2001). All the above laboratory findings underpin the hot

spots mechanism, and theoretical interpretations were proposed as well.

Quantitative research was conducted, based on the appreciation of incendivity of rock on rock friction, aiming to provide data which engineering controls can be based upon and developed. Rae from UK SMRE conducted systematic research on the criteria of rock on rock frictional ignition by making use of highly incendive sandstone (Darley Dalesandstone) with the outcomes, as shown in Figure 1. (Rae 1964).

Figure 1 shows that the mean sliding distance prior to ignition is in inverse relationship with the momentum of the sliding, the larger the momentum the shorter the sliding distance is needed; while the most highlighted feature in Figure 1 is the existence of the threshold mean sliding distance prior to ignition, which in this specific case is 5.44 m (1/0.1838). The existence of threshold friction distance prior to ignition is also demonstrated by the outcomes of the experiments conducted by Ward and Xu, as shown in Table 1 and Table 2 respectively.

Table 1 shows that, under Ward's experimental environment, the sliding distance prior to the frictional ignition decreases substantially with the increase of sliding speed and momentum; and even with the most incendive speed in the experiments, which was 5.1 m/s, the sliding distance prior to the frictional ignition was no less than 10.2 m (Ward et al. 2001). Table 2 shows that the dry conglomerate gave the highest incendivity; while even with the conglomerate against conglomerate under the contact pressure of 171–228 N, the minimum sliding distance before frictional ignition was 20 m (which is worked out with 10 m/s × 2 s) (Xu et al. 2007). The discrepancy of the minimum sliding distance prior to frictional ignition among the research outcomes of Rae, Ward and Xu, was due to the different contact loads and rocks adopted in their experiments. The maximum contact loads adopted in Rae's experiments were much higher than those adopted by the other two researchers, and were more approximate to the realistic adverse underground environment. Nevertheless, all these

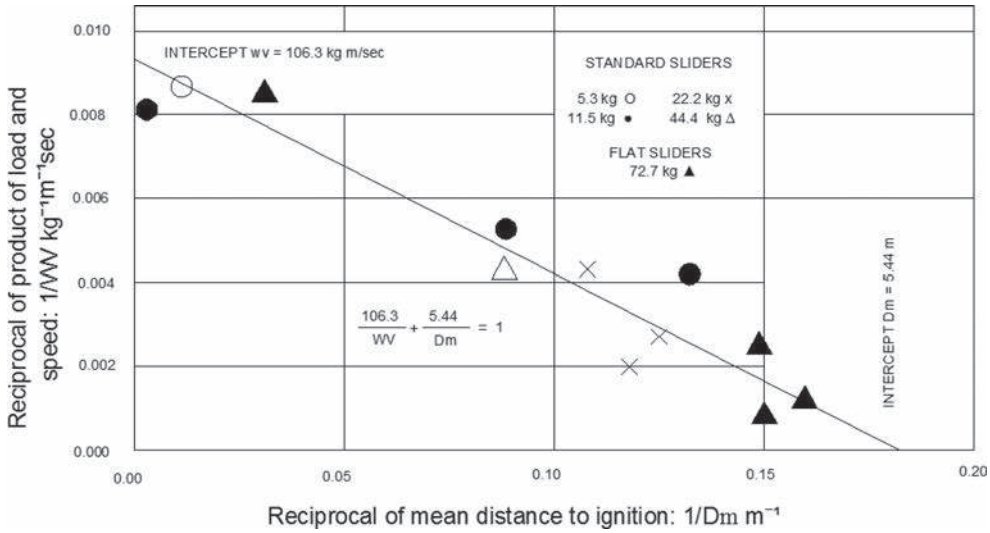

Figure 1. Tests outcomes from UK SMRE (Rae 1964).

Table 1. Sliding time and distance prior to ignition for different rock sliders using sandstone wheel from Appin Colliery (Sample A1) (Ward et al. 2001).

Wheel speed (rpm)	Wheel speed (m/s)	Time to ignition for different rock samples used as sliders (s)/distance prior to ignition (m)			
		M1 Claystone	A1 Sandstone	FB1 Quartzite	SB10 Siliceous coal
700	5.1	No ignition	12/61.2	2/10.2	2/10.2
500	3.7	No ignition	28/103.6	15/55.5	11/40.7
300	2.2	No ignition	No ignition	35/77	30/66

Table 2. Data from Xu's gas explosion induced by the rock friction experiments (Xu et al. 2007).

Rock type	CH4 concentration (%)	Contact normal force (N)	Sliding speed ($m \times s^{-1}$)	Sliding time (s)	Number of tests	Number of explosion
Gritstone on Gritstone	5~16	120~150	3	10~998	10	0

Conglomerate on Gritstone	5~16	171~228	10	6~32	10	8
Conglomerate on Conglomerate	5~16	171~228	10	2~32	10	8

research outcomes support that threshold sliding distances would be needed to yield incendive enough ignition sources.

The threshold sliding distance is backed by the heat requirement to yield incendive enough hot spots under the given experimental environment. According to the frictional heat accumulation theory, heat generated in the sliding process equals the normal stress load at the contact multiplies the dynamic friction coefficient and the sliding distance, as shown in Equation 1. The normal stress load at the contact cannot be infinite but limited by the rock strength and hardness, i.e. the force applied at the contact cannot exceed the strength of the sliding bodies; combining with the given heat requirement and the fixed range of dynamic friction coefficient in the defined environment, the minimum threshold sliding distance can be estimated with the following equation, in which the cooling procedure associated with the sliding is ignored.

$$Q = F \times C \times L \quad (1)$$

Where Q = the heat generated in the friction process; F = applied normal force at the contact; C = the dynamic frictional coefficient at the contact point; and L = sliding distance prior to the frictional ignition.

Besides the threshold sliding distance, the threshold sliding velocity is another decisive factor to yield incendive enough ignition sources. In the tests conducted by Rae from UK SMRE, the sliding speeds of 21.3 m/s, 10.6 m/s, 5.3 m/s, 5.3 m/s, and 1.6 m/s were found to be the minimum speeds under the contact loads of 5.3 kg, 11.5 kg, 22.2 kg, 44.4 kg and 72.7 kg respectively (Rae 1964). Ward's research also confirmed that the incendive rock on rock sliding under higher speed, which was 5.1 m/s, may lose its incendivity under lower speeds, which were 2.2 m/s and 3.7 m/s (Ward et al. 2001). Qin et al. conducted FI tests under two sets of sliding speed, which were 4.2 m/s and 7.43 m/s with the same experimental environment, and found that 4.2 m/s did not yield any frictional ignition while the speed of 7.43 m/s yielded 13 frictional ignitions out of the 29 experiments (Qin et al. 2005). In the tests conducted by Xu et al., the 3 m/s sliding speed did not yield frictional ignitions while 10 m/s sliding speed yielded frictional ignitions, as shown in Table 2. (Xu et al. 2007).

Cooling process associated with the frictional heating up is the underlying rational of the threshold sliding speed requirement. Blickensderfer conducted research on the cooling process of the trail of the sliding; and a cooling model was proposed and validated based on the research outcomes of the laboratory experiments; a typical cooling curve of the sliding trail based on the theory is shown in Figure 2 (Blickensderfer 1975). The theoretical model revealed that the lifetime of hot streaks on the trail of the contact point over the minimum ignition temperature of methane-air admixture stays within very short time, which is less than10 milliseconds; combining with the finding that a threshold area of hot spot is needed to ignite methane-air mixture under the given temperature (Powell 1969, Rae et al. 1964), and sliding width is fixed under a specific friction, then the area of the hot streaks with temperature over the minimum ignition temperature is indirect proportion with the sliding speed (Blickensderfer 1975). So, a threshold sliding speed is needed to reach or overtake the threshold hot spot area to yield an incendive ignition source.

In conclusion, apart from the frictional ignitions originating from pyrite sparks, which can burn in the air; in given environment, the eventuation of frictional ignition relies on the presence of

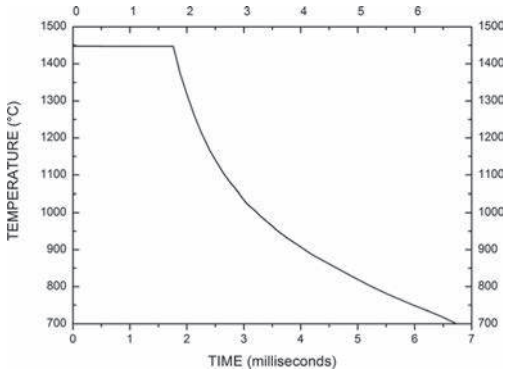

Figure 2. Calculated cooling curve of a narrow zone in the hot-streak trail (Blickensderfer 1975).

hot spots with enough incendivity. The presence of the incendive frictional ignition sources requires minimum threshold friction distance and friction speed.

2.2 *Ignition environment mechanisms*

From the perspective of ignition environment, even though it has been well established that the ignitable range of methane concentration is from 5% to 15%, the ignitable oxygen concentration is no less than12%, and the methane concentration of 7% has the highest incendivity (Ramsay et al. 1965, Rae et al. 1964, Cutler 1974); new concerns in this regard have arisen from the industry. One notable concern is the presence of liquid hydrocarbon; an underground coal mine in Utah, USA came across some liquid hydrocarbon in the coal measures strata, and U.S. NIOSH (National Institute for Occupational Safety and Health) laboratory experiments have confirmed that with the presence of the liquid hydrocarbon, the frictional ignitions are much easier to be triggered (Cash dollar 2008). Not only in USA, but somemines around other parts of the world are facing the presence of liquid hydrocarbons. Armstrong reported that oil occurrence has been observed in the three strata overlying the major active Bulli coal seam, among which, coal cliff sandstone directly overlaid on the coal seam, while Scarborough sandstone and Bulgo sandstone are the third and fifth overlying strata respectively (Armstrong et al. 2006). Although it has not been recorded in accessible literature, the presence of liquid carbon hydrogen in underground coal mines is not rare in China as well.

The incendivity of the environment can also be boosted by the increase of Virgin Rock Temperature (VRT). Theoretically, it has been supported by the frictional ignition predicting model developed by Blickensderfer, in which higher temperatures of the sliding bodies boost the frictional heating up and ease cooling speed as well as intensity of the trail (Blickensderfer 1975). The studies conducted by China Coal Research Institute show that the increasing of environmental temperature will significantly boost the incendivity of the rock friction (Qin et al. 2005); Qin et al. conducted rock on rock frictional ignition experiments under different environment temperatures (which were also the initial rock temperature) with the same other parameters, and found that clusters of sparks were seen with temperature reaching 10 °C while no sparks were seen under 5 °C (Qin et al. 2005). Even though the model developed by Blickensderfer included the temperature as a variable, no verifying experiments have been done by taking it as the independent variable, which can be done in further study.

Another concern on frictional ignition environment is the presence of higher incendive gas content in the methane-air admixture at some local areas, especially in the areas of oxidation and temperature rising zone in the goaf, where thermal decomposition gas product of coal volatile can be expected. The presence of these contents would increase the incendivity of the local gas environment (Li et al. 2012). This concern is backed by the research outcomes of methane, oxygen, and spontaneous combustion danger area distribution pattern in the goaf area. Chinese researchers conducted methane and oxygen concentration monitoring in the goaf area of U shape ventilation Longwall panel, and obtained methane distribution in the goaf area as shown in Figure 3 (Yang & Gu 2010).

Figure 3 shows that the explosive range of methane exists between 10 to 76 meters in by the goaf. Combining with previous research outcomes of the oxygen distribution pattern in the goaf under the spontaneous combustion research, which is that the heat elimination through ventilation zone is between 0 and 25 meters with oxygen concentration of 20 to 16 per cent, the oxidation and temperature raising zone is between 25 and 60 meters with oxygen concentration of 16 to 7 per cent, and asphyxiation zone with oxygen concentration of less than 7 per cent; it is highly probable that there are overlapping areas with explosive mixture of oxygen, methane and presence of gas products from thermal decomposition of coal volatile. It would be meaningful to further investigate the gas make of the product of thermal decomposition of coal volatile and its enhancing effect of the incendivity of the methane-air admixture gas body.

In summary, the presence of incendive ignition source relies on presence of threshold sliding distance and sliding speed for the incendive rocks; the incendivity of the environment can be boosted by the presence of liquid carbon hydrogen, the increase of virgin rock temperature, and the presence of the gas product of the thermal decomposition prod-

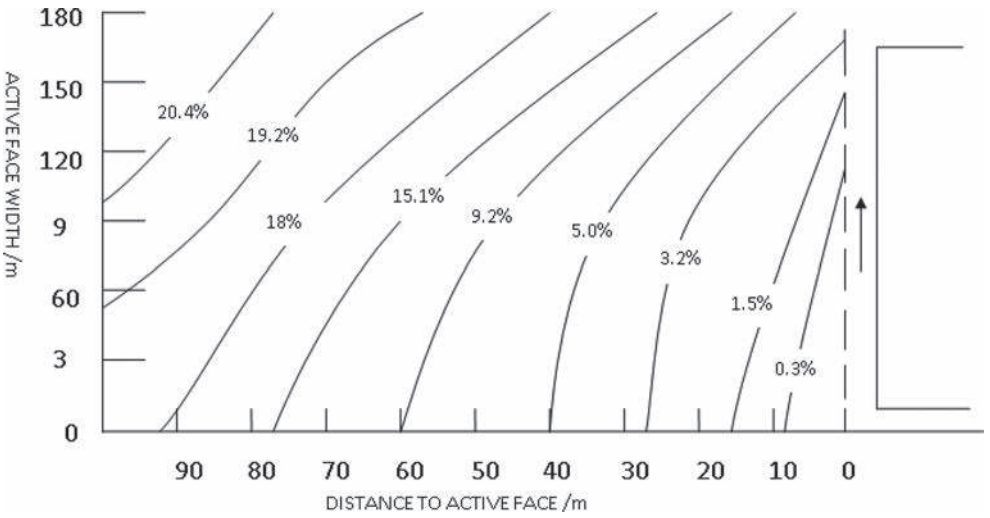

Figure 3. Methane distribution pattern in the goaf of a Longwall panel in China (Yang & Gu 2010).

uct of coal volatile. Although the mechanisms of ignition source have been systematically studied, the new concerns regarding the incendivity of the environment have just been preliminarily probed.

3 GFI CONTROLS

GFI controls are divided into two categories: frictional ignition source controls and frictional ignition environment controls. The rational underlying ignition source controls is to avoid the presence of the threshold values of the friction momentum, speed and distance. Frictional ignition environment controls rely on avoidance of the presence of methane air mixture in explosive range and the presence of the higher incendive thermal decomposition gas product of coal volatiles in the areas where incendive ignition sources are likely present.

3.1 *GFI source controls*

Forced or induced roof caving, goaf backfilling and partial extraction can all limit the possible friction speed between the rocks by controlling the freestanding height of the overhang roof, according to the terminal speed of free falling theory.

$$V = \sqrt{2gh} = 4.43\sqrt{h} \tag{2}$$

Where V = the terminal speed of falling rocks; h = the free-standing height of the overhang roof. Among these three control measures, forced roof caving is the most economical and practical one and has been adopted widely to tackle this issue (Yang & Gu 2010, Qin et al. 2003). Goaf backfilling and partial extraction have been adopted in some underground coal mines for surface subsidence control or resource recovery reasons, and are helpful for GFI control. The required forced caving height can be worked out with the following formula:

$$h_e - h_f(k-1) = H_{threshold} \tag{3}$$

Where h_e = coal extracting height; h_f = forced caving height; k = swell factor of the forced caving rocks; $H_{threshold}$ = the threshold free-standing height which can yield the threshold terminal speed.

Forced roof caving can avoid the presence of massive friction contact load by avoiding the weighting associated with the falling of massive volume of free standing roof. The presence of large areas (even up to hundreds of thousands of square meters) of free standing overhang hard conglomerate or sandstone roof has been reported in underground coal mines. The fall of such large area of rock would incur massive load at the contact point of friction, which would be very highly incendive. Forced roof caving with designed increment value will keep the falling rock mass within the designated range, which will significantly alleviate the load at the friction contact.

Forced roof caving can also avoid the presence of incendive sliding distance. By implementing forced roof caving with reasonable increment, the formation of rock blocks with large surface, especially plate-like falling of roof strata, which can provide incendive sliding distance, is avoided. In conclusion, the forced or induced roof caving can limit the possible friction speed between the rocks,

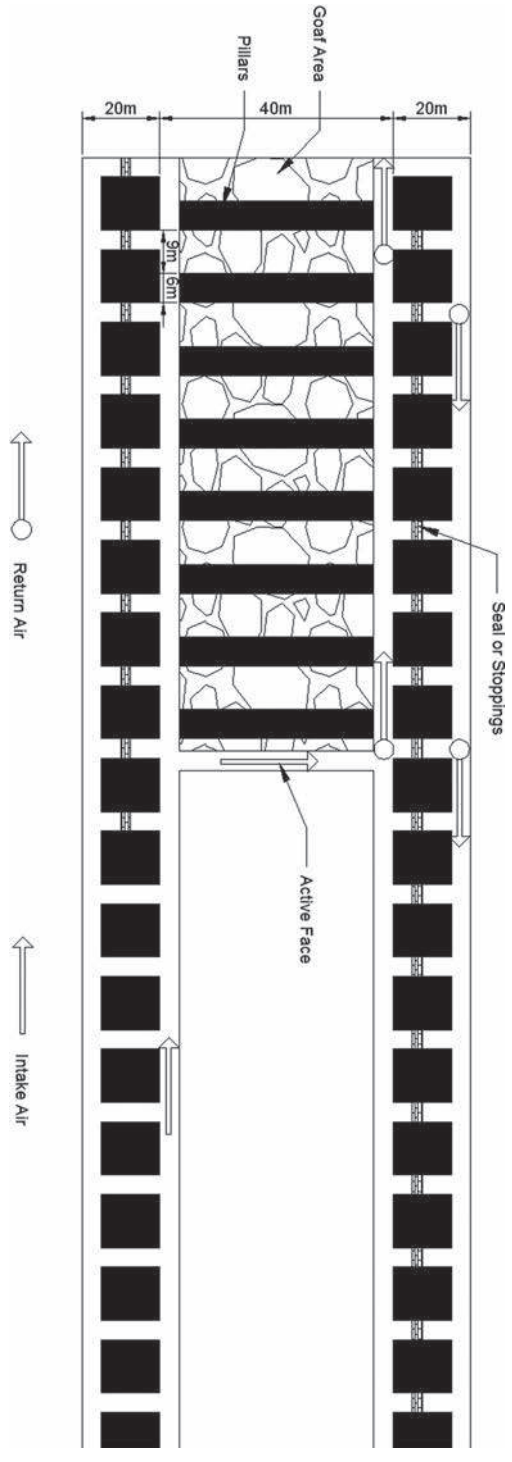

Figure 4. The use of a bleeder system to keep the methane concentration below the explosive range at a room and pillar panel (Qin et al. 2003).

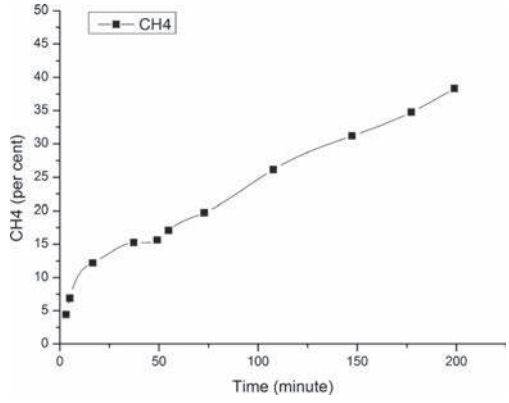

Figure 5. Methane concentration variation after rapid goaf sealing (Qin et al. 2003).

limit friction load at the contact, and avoid the presence of rock surface which can provide long enough sliding distance.

3.2 GFI ENVIRONMENT CONTROLS

Keeping the methane concentration beyond the explosive range is the most effective and preferable approach on this issue. To control the methane level below the explosive fringe under a particular panel ventilation system is mainly achieved by removing methane emissions from the goaf. Bleeder system has been widely adopted by the industry to achieve this; the bleeder system can take away the methane emission from the goaf or adjacent methane bearing strata, as shown in Figure 4.

Figure 4 shows the use of a bleeder system. The on-site monitoring results showed that the outcome was very satisfactory; the methane concentration of the general gas body was kept below 3% after the coal face had passed over 80 meters (Qin et al. 2003). However the bleeder system should not be adopted in coal faces with a high risk of spontaneous combustion.

Rapid goaf sealing technology is another practical approach to keep methane concentration beyond the explosive range. If the goaf can be sealed tightly within short time, methane emission from the goaf can be isolated, which would promptly raise the methane concentration in the goaf and simultaneously reduce the oxygen concentration to below the lean flammability limit; thereby the risk of frictional ignition can be eliminated (Qin et al. 2003). In June 2001, an industrial trial was conducted in an underground coal mine in China with a rapid goaf sealing method; the goaf was sealed with around 30 minutes. After the sealing, tube bundle was used to monitor the gas

content on the goaf side of the seal, and the results are shown as in Figure 5 (Qin et al. 2003).

Figure 5 shows that within around an hour after goaf sealed off, the methane concentration of the general gas body on the goaf side of the seal passed the explosive range. The rapid goaf sealing technology is not universally adoptable; it cannot be applicable in active Longwall panel but is very effective in room and pillar or hydro mining panel as shown in Figure 4, especially after a large scale plate-like roof fall, which might create a very favorable condition for the incendive rock on rock friction.

4 CONCLUSION

GFIs in underground coal mines pose a serious safety threat that may potentially lead to major gas explosions or fires. This paper provided an examination of GFI incidents and their underlying mechanisms. The eventuation of frictional ignition incidents relies on co-presence of both incendive ignition source and incendive environment. The presence of incendive ignition source depends on two critical and decisive parameters, i.e. the friction distance and friction speed. The incendivity of the environment is generally determined by the methane, oxygen concentrations, and can be boosted by the presence of liquid hydrocarbon, the increase of virgin rock temperature, and the presence of hydrocarbon gases from thermal decomposition product of coal volatile. Effective control measures can be developed to limit the friction distance and friction speed associated with rock falls in the goaf, therefore avoid the development of an incendive ignition source; they can also be developed by keeping the methane-air admixture beyond the explosive range. These control measures include forced or induced roof caving, bleeder ventilation system and rapid goaf seal-off.

ABSTRACT: Hazards due to stratum separation are a type of roof water hazards that unexpectedly happen even without any water reservoir. However, the hazard origins have not been understood or explained, resulting in great difficulties in control of water hazards in coal mines. To solve the problem, Haizi Coal Mine is taken as a case study. The hydrogeological, geotechnical and mining conditions are analyzed in a case study in Haizi Coal Mine. The roof stratum failure and displacement are analogized physically and simulated numerically. A new type of water hazards is found finally, and a new theory for the mine hazards, i.e. water hazards caused by burst of water cells formed by overburden stratum separation, is put forward. The drilling and borehole camera scanning have verified the above theory. According to the theory, the dynamic draining measures are proposed and used successfully in the control of the water hazard. The research achievements are applied to other working faces with the similar hydrogeological conditions for coal mining safety. The investigation on the hazards by simulations not only theoretically fills the gap of water hazard classification for coal mines, but also finds a way for the control of water hazards in coal mines.

1 INTRODUCTION

Roof water hazards under simple hydrogeological-condition at some coal mine occurred at China's Yili in Xinjiang province, Huanglong in Shanxi, Hongliu of Shendong mining area, Zaozhuang in Shandong, Laohutai in Liaoning, Wanbei in Anhui and so on in recent years. Water hazards from roof at working face 745 in Haizi coalmine of Huaibei Mining Group Corporation with the capacity of 3887 m^3/h resulted in five workers' death in 2006; Roof water inrush with rock happened in Yili and resulted in 16 workers' death in 2002; The same kind of hazard happened in Laohutai coalmine in Inner Mongolia, causing 19 workers' death in 2004. Several inrushes took place in Hongliu coalmine, Shendong mining area. However, this type of hazards had not been controlled, and its origins had puzzled scientific and technical personnel in water hazards prevention and control. The author conducted a series of investigations in this type of hazards, mechanical model derivation, analog experiments, numerical simulation, and finally find that the water reservoir is due to roof stratum separation—a new type of water hazards. The conclusion is drawn that the burst of water cells formed due to overburden stratum separation (Meng 2007, Wang 2003, Mining Institute 1981) happened under the action of impact pressure by means of hard roof-caving.

Roof separation is a common phenomenon in overburden during coal mining. Some specialized researches (Su, et al 2002) on formation mechanism of roof caving and mechanicalmodelling about roof caving had been done by some scholars before, including analog experiments, numerical simulations, such as simulations in the discrete element method (Xu, et al 2004, Cao, et al 2000), in finite element method (Su, et al 2003), in contact element method (Zhang, et al 2008) and in finite difference method (Chen & Wang 2008). Roof stratum impact also has been deeply researched in our country, involving the stratum structure (Meng 1997, Pan 2005), the key strata analysis method (Qian, et al 2003) and fuzzy mathematics method (Liu, et al 2006). It is generally believed that roof impact bias is related tothe lithologic structure of the roof, and the formation of impact pressure is the process of the accumulation and rapid release of energy before and after the failure of tight roof. However, water hazards due to overburden stratum separation under the action of impact pressure have never been reported before. Therefore, this is a new type of water hazards. It is significant in theory and in practice for researches this type of water hazards in order to enrich the classification of water disasters, identify the hazard causes, and finally develop control measures

2 THE HYDROGEOLOGYCAL ANALYSIS OF HAZARD ORIGINS DUE TO STRATUM SEPARATION

2.1 *Hydrogeologic condition of haizi coalmine*

Haizi Coalmine is located in Linhuan mine area, Huaibei coalfield, North China coal basin. The mine strata dip overall to the north with angle of 10° to 30°. Working face 745 is located in the east wing of mining district 84. The parameters of the face are: 403 m. of the average overburden of coal seam, 350 m in length, 70~120 m in tilted width, s18° in dip angle, 0.2~3.2 min coal thickness. The comprehensive mechanized mining method was applied. Natural collapse method was used to manage roof. The strata from the roof are followed by argillite, siltstone and fine argillite, sandstone and dioritic porphyrite. The main aquifer of the mine field includes sand-gravel layer at the bottom of quaternarysystem, the sandstone aquifer in the overburden of the seam, the limestone aquifers of Taiyuan group and Ordovician limestone aquifer. The quaternary system aquifer is too far away from the working face 745 to cause any hazards to the working face. Ordovician limestone aquifer lying 150 m under the coal floor is too far to cause any hazards either. The sandstone aquifer in the overburden is the only aquifer to have some effect on mining with small amount of water flow. 16 water inrushes happened in 4 working faces in mining district 84 when coal 7# was mined since August in 1998. In the inrushes, 4 was less than 50 m^3/h of water flow, 7 is less than 100 m^3/h, 4 is less than 150 m^3/h, 1 is 211 m^3/h. These water inrushes all happened in the mined areas and never caused any disasters.

However, roof water hazards at this working face happened at in May 21, 2006, with 3887 m^3/h of flow, nearly 500 m^3 of waste rock and caused 5 lives loss.

2.2 *The hydrogeological analysis of hazard origins due to stratum separation*

According to the mining theory, the caving-in zone, permeable fractured zone, flexural-subsidence zoneformed after mining. Under normal circumstances, flexural-subsidence zone is gradient with permeable fractured zone, and gradually develops to the surface, resulting in surface subsidence. Flexural-subsidence zone reach the surface rapidly if top part of the overburden is sand (Dong & Wang 2007), while the subsidence caused by the hard roof failure occurs slowly. Through the analysis of the borehole histograms, 80 m of intrusion rock in thickness is 50–60 m above the roof of coal 7 in Haizi Coalmine. According to the key stratum theory, the hard roof is the key stratum to bear gravity. The hard rock over the roof would not bend synchronously with the underlying soft rock because its inflexibility is larger than the lower one so as to form separations between strata in the overburden. Because the bottom layer of separation is aquiclude, a big water cell forms by the recharge from sandstone aquifer. When the space of overburden stratum separation is too large, the key stratum in the roof of the separation will break, and then the cells burst because of huge impact stress, and so that the water hazards occurred, as shown in Fig 1. According to statistics, many coal mines with similar hydrogeological conditions suffered from roof water inrush as heavy as Haizi coal mine. The specific conditions is shown in Table 1. The common characteristics of the hazards are momentary, swift and violent process with debris.

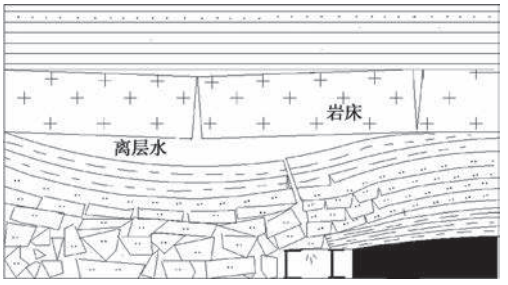

Figure 1. Secondary abscission layer formation water disasters.

Table 1. Hdrogeological conditions to cause water hazards due to stratum separation.

Coalmine	Mining height/m	Hard roof thickness/m	Distance to coal/m	Hazards
Haizi	2.6	70	50–60	5's death
Yili	3.3	30	41	16's death
Huang. lin	0.8–6.75	71.19	>25	9's death
Hongliu	5.3	40.6	51.2	Major danger
Laohu. tai	18–25	30	75	19's death

3 THE ORIGINS OF WATER HAZARDS DUE TO ROOF STRATUM SEPARATION

3.1 *Mechanicalmodel*

The strata above the working face can be simplified as a beam fixed at both ends. It is assume that there are n strata named 1, 2, 3… n in turn above the coal seam. Based on the knowledge of material mechanics, when the beam fixed at both ends

bends, the maximum curvature and deflection are as follows:

$$\rho_{\max}(i)=\frac{\gamma_i L_j^2}{2E_I m_i^2} \quad and \quad \varpi_{\max}(i)=\frac{\gamma_i L_i^4}{32Eim_i^2} \tag{1}$$

In the formula, γ_i: the bulk density of No. i stratum, *Li*: the span of No. i stratum; *Ei*: the elastic modulus of Mo. i stratum; mi: the thickness of No. i stratum. If the curvature and deflection of the adjacent stratum satisfy the followings:

$$\begin{aligned}\rho_{\max}(i)\geq\rho_{\max}(i-1)\\ \varpi_{\max}(i)\geq\varpi_{\max}(i-1)\end{aligned} \tag{2}$$

the strata will bend synchronously, othervice the strata will bend separately, as shown in Figure 2. Based on the knowledge of material mechanics, the stresses in curvature center and deflections are maximum when the beam is fixed at both ends. Therefore, the working face where people work is the most dangerous place because of water inrush.

3.2 *The analog experiment*

In order to verify the view that water hazards due to stratum separation, the experiments with similar materials have been done on basis of mining conditions, roof lithologic characters and boundary conditions at working face 745. According to the three laws of analog simulation, the parameters of the materials is shown as Table 2.

The analog experiments were conducted on a plane stress model and a 3-dimensional model. The plane model is 1 m high, 3 m long, and 0.3 m wide. 55 observation points were fixed in the model, including 39 pressure points and 16 displacement points.

Through the observation, the movement of overlying strata is in layer way or in group way. The weak strata's movement is attached to the strong and thick strata's movement, as shown in Figure 3. Observation points 40#, 44#, 48#, and 52# were 17.5, 17.5, 43.3, 52.3 cm above coal roof, and the last two are located in igneous rock bed. From Figure 3 we can see that: ①The displacements of roof strata is divided into two groups by the bottom of igneousrock (the gray rock in Figure 3). The vertical displacements of two points (No. 40#, 44#) in coal strata under igneousrock bed is much larger than those of two points (No. 48#, 52#) in igneous rock bed, resulting in strata separation. The two points in coal measure strata start to move at the same time, and the difference beteen the movements is obvious, while thetwo points in igneousrock began to move consistently, but difference two displacements. is little. ② Closer the strata

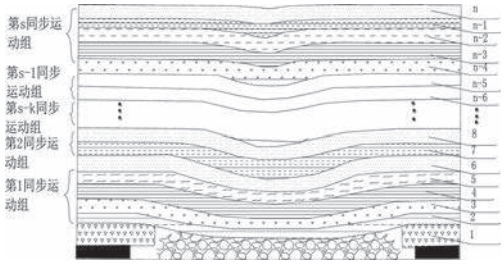

Figure 2. the strata bend synchronously and separately.

Porphyrite	2.76	131.50	12.8	1.59	0.570	9:0.9:0.1	4.48	48.1	8.2	0.32

Note: MaterialRatio: sand: calciumcarbonate: gypsum = 1:1:1

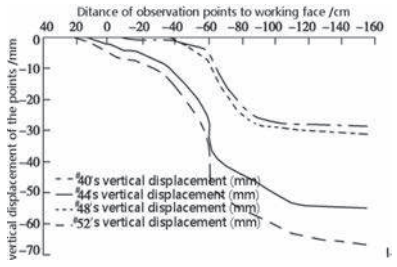

Figure 4. Vertical displacement curves at different positions in line 2 in overburden strata.

to the coal roof is, larger is the displacement. The displacement of point 40 > point 44 > point 48 > point 52. Closer the roof strata to the coal is, the less is the displacement of the stratum separation, but they fractured obviously. The strata (the white layers in Figure 3) close to the igneousrock separate obviously, as shown in Fig 4, but they did not fracture obviously—bending was the main deformation. This means that the surroundingrock of the stratum separation is characterized by impermeability and is favorable to form a water sell.

2.3 *The numerical simulation of FLAC3D*

Advance support stress zone of the coal wall is 10–14 m wide through the observation in Haizi Coalmine before, and the compacted zone is 60–75 m in the goaf after mining. The height of fractured zone is 8–10 times of the mining height, while the failure depth of floor is 10–12 m. According to the conditions of the working surface, the scope of the numerical simulation is 200 m long (60 m before and after the wall, 80 m of the mined area), 520 m wide (150 m upper and lower from roadway), 238 m high (55 m of floor in average, 169 m of roof). The floor elevation of the model is –395 m, while the roof is –157 m. The mechanical parameters are shown in Table 2.

With the same geometry with physical simulation, the model is divided into 68640 grids, 73677 nodes. Both the lateral sides and bottom are constrained by simply-supported structure, and the lateral sides are fixed for horizontal displacement, while the longitudinal displacement is allowed. Longitudinal displacement of the bottom is fixed, while the horizontal displacement is allowed.

Failure criterion is based on Coulomb Mohr Strength Theory. The results of the simulation is shown in Figure 5 and 6. As can be seen in Figure 5, just above the working face, the stress of igneousrock is $-0.15 \times 10-6 \sim 0.0$ Mpa, and the stress of coal measure strata is $-5.5 \times 10 \sim -5.0 \times 106$ MPa. The simulation also shows that stress gradient changes suddenly at the interface of strata separate obviously.

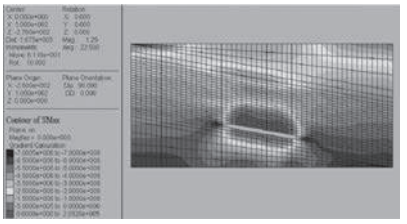

Figure 5. The maximum principal stress contours of surrounding rock.

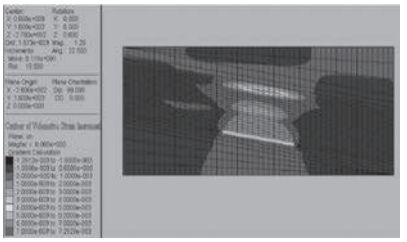

Figure 6. Contours of volumetric strain increment of surrounding rocks when working face advances 40 m.

The strain gradient change suddenly too in the interface of igneous rock and its covered layers, when working face advances 40 m as shown in Fig. 6. There is some difference between the results of the FLAC simulation and RFPA simulation used by literature[7], due to the difference of the structure of stratum and layout of excavating. As is shown in Figure 6, when the advance distance of mining working face is 40 m, volumetricstrain concentration behavior of the stratum under igneousrock occurred, and the stratum separation is obvious.

2.4 *Numerical simulation of distinct element code*

The two-dimensionalmodel is 200 m long, 138 m at vertical direction, 2.5 m of miningheight, and the grid partition is shown in Figure 7. The caving pace of main roof is 10 m. The load of upper boundary is applied by 300 m deep rock's weight, and the lower boundary is fixed in vertical direction. The left and right bordarys are fixed inhorizontal direction. The mechanicalparameters are shown in Table 2. Uatural caving method to manage the roof during mining.

The numerical simulation shows that the stratum separation under igneous rock is not obvious when the working face advanced for 200 m. The Figure 8 shows that stratum separation between igneous rock and its covered layers is obvious when the working face advanced for 250 m and 300 m, as seen in Figure 9 and Figure 10. The space of stratum separation becomes obviously bigger and bigger with the advance of working face.

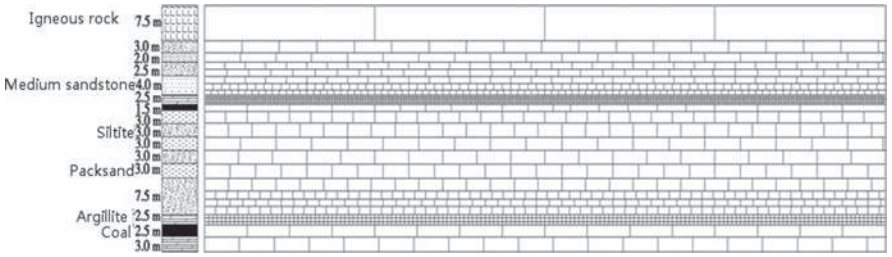

Figure 7. Roof stratum column and discrete elements for working face 745.

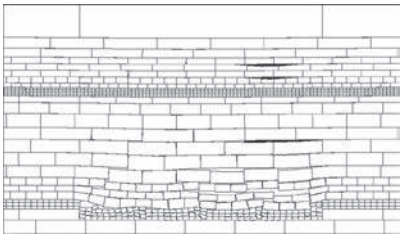

Figure 8. Roof stratum separation when working face advances 200 m according to discrete element simulation.

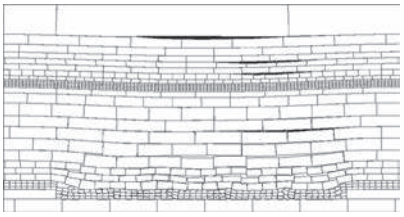

Figure 9. Roof stratum separation when working face advances 250 m according to discrete element simulation.

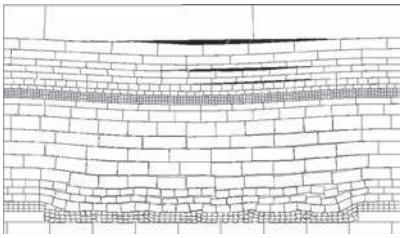

Figure 10. Roof stratum separation when working face advances 300 m according to discrete element simulation.

The results of UDEC simulation are accord with the key stratum theory (12). From the lithology we can see that there are four sub-key strata (three fine sandstone strata of 3 m thick and one medium sandstone of 5 m) and one main key stratum (thick igneous rock) in the roof of working face 745. The stratum separation formed in the bottom of sub-key stratum at first. When the first key stratum broke, the stratum separation occurred in the second key stratum. Then it developed to the third key stratum, and it ended in the main key stratum.

4 THE PREDICTION AND CONTROL OF THE WATER HAZARDS DUE TO STRATUM SEPARATION

Targeted measures was taken to control the water hazards according to the knowledge of stratum separation origins, that is to drill borehole to the water cells in the upper and lower roadways in the direction against advancing to drain as shown in Figure 11. In order to ensure that the bore would not be plugged due to the roof failure ahead of working face, water-pervious drivepipes were embedded in the bores.

This technology of mining-drainage obtains good results in application in the 1 st working face at Shendong Coalmine, in which average mining height is 5.3 m, and the roof strata consist of sandstone and argillite with 51 m in thickness. The water inrush started in the goaf when the working face advanced for 39 m, and water flow increased from 15 m^3/h to 212 m^3/h. The water inrush happened again with flow 1817 m^3/h when the face advanced for 55 m, seriously threatened the safety. The hazards were caused by quick-release of water from roof stratum separation. In order to prevent the hazards from happening again, six stages water drainage engineering were exercised anticipative goal was reached. 16865 m^3 of water were drained out within 20 days in the first stage of engineering. The waterinflow boreholes is shown in Table 3. Playing the same effect with the first one, the other 5 stages of drainage engineering are omitted here.

5 CONCLUSIONS

According to the analysis of hydrogeological conditions, mechanical model of the roof caving and bending, analog experiments, distinct element

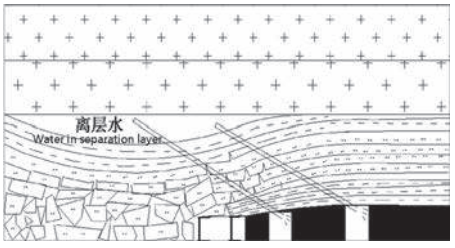

Figure 11. Layout of boreholes for roof cell water draining.

Table 3. The water quantity of drilling in the first drainage test at working face.

Borehole	aqf above coal m	Initial flow m^3/h	Max flow m^3/h	Average flow m^3/h	Total water value m^3
T2–3	44.84	10	40	15.71	6156.7
T2–2	55.05	8	60	0.26	83.9
T2–1	58.17	4	10	4.45	926.6
T3–3	60.49	27	85	38.06	6393.9
T1–2	58.82	9	90	45.89	3304.0

simulations and site observation at working face. The conclusions are drawn as follows:

1. The necessary condition to form a water cell is the combination of hard stratum and weak aquiclude below. The thicker hard stratum is, the bigger separation space will be. The more groups of strong—weak strata combination, the more separation cells will be.
2. The mining analog experiment demonstrated that the vertical displacement of hard rock stratum is much less than that of weak rock stratum in the same vertical line and obvious separation space occurred between hard and weak rocks in the mining process. The experiments confirm the results with th numerical simulation and key stratum theory.
3. The upper hard layer impact failure is cause of water cell break or water hazard.
4. The drilling through the water cell in the direction against advance to drain is the effective method to control the water hazard caused by water cell burst.

ABSTRACT: In order to effective pre-assessment on the potential danger of the rock burst to the coal working face, a multivariate Analytic Hierarchy Process (AHP) is proposed based on the hazard zone and the hazard extents. The influencing factors of rock burst can divided to five sections, including mining depths, coal and rock structure, geological structures, overlying strata spatial structure and pillar induce. In this paper, a model was established using AHP. To define the single factor, a judgment matrix was constructed. To evaluate the single factor on a specific working face several methods were adopted, for example the theory of mining pressure and strata control, the project analogy method and the numerical simulation analysis. First, through the evaluation of single factor using a proper method, the hazard zone formed by a single factor was defined. Then, the interaction relationships among these impact factors in inducing rock burst were comprehensive analyzed. When a zone was simultaneously affected by several factors, the multi-factor coupling evaluation method was used to assess the hazard zones and the hazard extents. The proposed model was applied to evaluate the risk of rock burst, using the No.5305 working face in Jisan Coal Mine as a case study. The hazardous zones with different extents were confirmed. The prevention and control measures were used in advance and received a good effect. The feasibility and validity of the model for hazardous zones and hazard extents of rock burst was tested and verified.

1 INTRODUCTION

With the increment of exploiting depth, more and more coal mines are threatened by rock burst which occurs more and more frequently. It leads to seriously properties losing and casualties. Poland government ruled that coal mines must submit an evaluation report of rock burst risk before working face mining, and prevention and control measures should be formulated simultaneously, then the report and these measures were to be checked and modified strictly. This received a good effect (Ji Z, Sun C & Jiang F. 2008). Therefore, it's necessary to conduct a previous evaluation in the longwall mining working face under the condition of potential rock burst risk.

In terms of hazard evaluation of rock burst, many researchers have presented different evaluation methods. AE method of evaluating the danger of rock burst is presented (Dou L, He X & Bernard D. 2000).Weight-variable identification model of comprehensive evaluation on burst liability of coal and rock is built (Zhang K. & Xia J. 2004). By means of the in-situ stress measurement and calculation of stresses by non-linear finite element method, the effect of in-situ stress on rock burst was analyzed; a criterion is set up, based on the strength testing of coal; the criterion of energy is put forward to evaluate the risk of rock burst in the light of engineering practice (Yin, et al. 1997). Model of set pair analysis for evaluating rock burst risk is established in coal mines (Zhang, et al. 2011).Evaluation model of rock burst risk in mining based on blind data theory is presented (GAO, et al. 2010). Model of fuzzy comprehensive evaluation on rock burst danger in coal mine is presented (Yi, et al. 2011). Research of prediction model of rock burst in coal seam based on fuzzy neural network is presented (Liu X. 2008). Prediction and control of rock burst is conducted by evaluating rock mass stress (Chen X, Sun S. & Zhang B. 2002). Macro-evaluation method of rock burst risk in an "Isolated Island" working face is presented (Yu Z, Jiang F & Gui B. 2011).

Bayesian discriminant analysis is used for predicting coal and gas outbursts (Wang, et al. 2010). A coupled artificial neural network and fault tree analysis model to predict coal and gas outbursts is presented (Zhang R L & Lowndes I S. 2010). The catastrophe progression method in predicting coal and gas outburst is presented (Zhang, et al. 2009). A finite element perturbation method for the prediction of rock burst is presented (Sharan 2007). Fractal character and mechanism of rock bursts is presented (Xie & Pariseau. 1993). The Seismic Moment Method was applied to predict coal face rockbursts and microseismicity in deep longwall coal mining (Fujii Y, Ishijima Y & Deguchi G. 1997). The prediction method of rock-burst based on overlying multi-strata spatial structure theory is presented (Wang, et al. 2009).

Methods aforementioned all have received better effects, nevertheless it is difficult to evaluate rock burst hazard effectively by the presented evaluation methods with increasing of exploitation depth. the major performances are as follows: (1) it feels overtheoretical, not-easy to learn, and inconvenient to apply in site; (2) Most of these methods are used for macro evaluating for a whole working face or a mining area, while rock burst risk level in different zones of a certain working face is different; (3) the evaluation is implemented incompletely, only aiming at one or few influence factors. (4) More static evaluation methods are presented, lack of dynamic simulation evaluation with the process of face mining.

On the basis of engineering practice and theoretical research of rock burst prevention and controlling, overlying multi-strata spatial structure theory is applied to simulate longwall mining, and then multi-factor analytical hierarchy process evaluation method of rock burst risk is presented, based on geological, mining, and mining boundary conditions of longwall mining working face. The purpose is to investigate a practical, targeted and operable method, which can be applied to beforehand evaluate the potential dangerous areas and criticality, in order to meet the engineering requirements in site.

2 FACTORS INFLUENCING ROCK BURST AND CORRESPONDING EVALUATION METHODS

There are plenty of influence factors on rock burst, and the mechanism is complicated. For customized evaluation of rock burst risk, influence factors induced rock burst need to be analyzed by selecting appropriate evaluation methods, with the condition of specific zone and mining conditions.

2.1 *Factors influencing rock burst*

Whether rock burst occurs in bursting liability of coal seam which had been tested, the dominating influence factors are as follows:

(1) Exploitation depth

The pre-mining status of stress can be described by vertical stress and horizontal stress. The vertical stress and horizontal stress are both compressive stress, and the horizontal stress is the force derived from the vertical stress. Vertical stress increases in direct proportion with the increasing depth, but the horizontal stress, exceeding a certain value of depth, is non-linear with increasing depth. Increasing extent is different along with properties of the surrounding rock, and the basic variation is that the increasing proportion along with mining depth is expanded gradually. Consequently, the deeper mining depth and the higher stress level are more liability to burst. It is generally acknowledged that the critical depth of bursting is 500–600 m in a single gravity stress field.

Different depth ranges, due to the influence on mining depth, are classified as an interval of 100 m.

(2) Coal and rock structure

Coal and rock structure refers to coal and rock strata, rock set and key strata, which may induce rock burst, also be called bursting strata. Bursting strata are divided into the single stratum and combined strata, therefore, the motion effects of a single bursting stratum and the spatial structure of combined strata need to be investigated. Single stratum includes hard roof, hard coal seam, hard floor and key strata; combined strata refer to the combination of the single stratum aforementioned.

According to transferring strata beam theory (Song 1989), abutment pressure distribution along the strike and dip in longwall face is related to strength and motion evolution of rock beams themselves. The lower coal strength, the higher strength of rock beam, the extent of abutment pressure will be larger, consequently the coefficient of stress concentration becomes small and the risk of bursting will be diminished. Conversely, the higher coal strength, the lower rock beam strength is lower, so the extent of the abutment pressure will be greater and the stress concentration coefficient becomes large, the risk of bursting is higher. According to the theory of key strata (Qian, et al. 2003), mine earthquake or rock burst is to be induced by key strata instability.

The factors of coal and rock structure for rockburst risk are included hard roof (main roof), hard coal, hard floor and key strata et al. Different combinations represent distinct dangerous levels. For example, Huafeng Coal Mine, which the characteristics of coal and rock structure are hard main

roof, hard coal seam, hard floor and huge thick conglomerate overlying, is one of most bursting threatened mines in China. Additionally, there are other types of coal and rock structure.

(3) Geological structure

Practice has proved that the tectonic stress resulting in rock-burst mines is relatively greater in the zone near geological structures where coal seams get thinner or have changing inclination, where tectonic stress appears, and where stress occurs in faults, folds, coal seams and strata. As a principal factor inducing rock burst, the tectonic stress generated from fault activation and anticline has a significant influence on producing rock burst. Stress largely concentrates on the shaft and fault of anticlines, so the rock bursts and mine earthquakes occurring in adjacent working faces or mines have close ties to the faults and structures of the anticline. When a working face is close to these structures, it will suffer from a significantly increased and intensified rock burst.

Around the zone where coal seams get thinner and where faults, folds and other geological structures occur, the tectonic stress resulting in rock-burst mines is relatively greater. As a principal factor inducing rock burst, the tectonic stress generated from fault activation and anticline has a significant influence on producing rock burst. Stress largely concentrates on the shaft and fault of anticlines, so the rock bursts and mine earthquakes occurring in adjacent working faces or mines have close ties to the anticlinal structure and faults. When a working face is close to these structures, it must get work prepared for pressure relief and prevention in advance. In this paper, the microseismic monitoring approach is used to study the classification of structure-controlled bursts and how to make an early warning, and it is proposed to divide the structure-controlled bursts into 2 types, i.e., pressurization and decompression.

(4) Spatial structure of overlying strata

Jiang has proposed a theory on the spatial structure of overlying strata (Jiang 2006), which refers to the three-dimensional structure formed after the rupture of overlying strata, including macroscopic hinged structures in the rupture zone and mesoscopic fractures at the edge of rupture zone, namely, the "θ" type of island mining face with four-side goaf and a support in the center, the "O" type spatial structure of mining face with one-side goaf but without a support in the center, the "S" type spatial structure of mining face with double-side goaf, and the "C" type spatial structure of island mining face with three-side goaf. As the spatial structure of overlying strata forms, the rupture and high stress field of the roof and floor are transferred and thus rock bursts may be induced.

The spatial structure of overlying strata mainly affects the following phases in push-mining of working faces, namely, the phase when the basic roof fractures for the first time, the phase in the square of working faces, the phase in the square of double working faces, the phase in the square of tree working faces, and the phase in periodic weighting of main roofs. Based on the above phases, we can differentiate the risk zones of rock burst, which are affected by the spatial structure of overlying strata.

(5) Induced by coal pillar

Coal pillar is an isolated body during exploitation. Since the presence of residual coal pillar, the stress field of coal pillar is different from that of other areas. Island-shaped or peninsula-shaped pillar may sustain the bearing pressure caused by multiple goaf directions. Not only the pillar itself is prone to burst, but also the upper pillar will pass concentrated stress to the lower pillar, which is consequently easier to suffer from rock burst.

Supported by the remaining pillar, the upper rock did not break or subside, while the surrounding rock above the goaf has broken and subsided, so there definitely exists high stress above the goaf area around the coal pillar. Taking the coal pillar as a center, there are pressure zone and strong shear zone extending outward. The following two theories can explain how rock burst occurs in coal pillar area: ① the theory on the burst of high-risk areas far from the coal pillar. It means that the high stress difference generates a strong shear force, resulting in fracture and release of rock burst induced by elastic energy; ② the theory on the burst of high-risk areas close to the coal pillar. It refers that the coal pillar itself loses stability under strong shear force and thus induces rock burst. Therefore, the strong shear is the root cause to induce rock burst.

The hazard of rock burst, which is affected by coal pillar, can be evaluated by calculating the stress concentration factor of coal body, and a quantitative analysis on different stress concentration factors is possible when dividing those factors into several levels: 1.5 ~ 2, 2 ~ 2.5, 2.5 ~ 3 and >3.

2.2 *Evaluation methods of rock burst risk*

Different evaluation methods based on various factors, the main evaluation methods are underground pressure and strata control analysis method, engineering analogy method and numerical simulation analysis method.

(1) underground pressure and strata control analysis method

Underground pressure and strata control analysis methods mainly contain that whether the stress

induced by mining reaches to the stress level of bursting, whether the difference of high stress would be generated by strata motion, how much is the high stress magnitude of the difference, and the dynamic distribution of mining stress field. Instability of the key strata, of which the characteristics and the influence of mining need to be analyzed, would induced rock burst or mine earthquake. The dangerous zones can be determined by stress level and status of coal and rock.

(2) engineering analogy method
Through similar conditions, there is something in commonality and differentia of bursting. The longwall face to be evaluated is analogy with the ones adjacent or other mines burst, to identify commonalities and determine the dangerous zones and magnitudes.

(3) Numerical simulation analysis method
Numerical simulation analysis method is an approximate method, such as boundary element method, finite element method, discrete element method and discontinuous deformation method (DDA) etc. It is assumed that the coal and rock mass is homogeneous and isotropic, and can simulate the stress distribution and concentration in certain mining areas, sequentially analyze the magnitudes of bursting risk. Investigations on rock burst are presented using numerical simulation analysis method, which has become a powerful tool for rock mechanics and rock engineering.

2.3 *Multivariate hierarchical evaluation*

The multivariate hierarchical analysis and evaluation on rock burst hazard refers to the process of determining the risk zone through univariate evaluation by applying mining pressure theory and approaches like engineering analogy and numerical simulation. Such process is based on the conditions such mining depth of specific faces, coal structure, geological structure, spatial structure of overlying strata and mining boundaries. The factors inducing rock burst may act individually or work together, and the same region may be influenced by several different factors, which will lead to local stress concentration. Make a comprehensive analysis on the act of these factors in inducing rock burst, adopt multivariate hierarchical analysis, build a judgment matrix, calculate the feature vector and the maximum eigenvalue and check their consistency, comprehensively analyze the weight of various factors on inducing rock burst, and evaluate the risk factors when the same area is influenced by several factors at the same time. The higher the burst risk factor, the greater the risk degree. The evaluation results serve as a basis to determine the three levels of areas with varying risk degrees: general risk zone, moderate risk zone and high-risk zone.

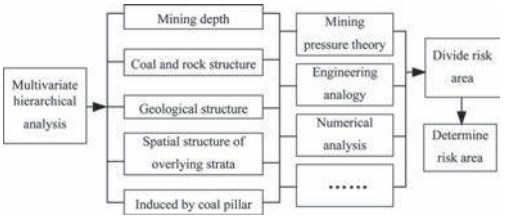

Figure 1. Roadmap of evaluation technologies.

Fig. 1 is the technological roadmap of evaluating the rock burst hazard of working faces through multivariate hierarchical analysis.

3 METHODS ESTABLISHMENT OF EVALUATION MODEL

Analytic hierarchy is an approach proposed by the American professor Saaty for a hierarchical analysis on decision weights (Saaty & Alexander. 1989). The approach makes a combination between quantitative analysis and qualitative analysis, applies the experience of decision-makers in determining the relative importance of criteria measuring whether goals can be achieved, gives a reasonable weight to each criterion of all decisions, and obtains the priorities of those decisions by the weights, thus effectively applying to those projects difficult to be resolved by quantitative methods.

Based on the nature of issues and the overall objective to be achieved, analytical hierarchy process decomposes the issue into different constituent factors, and arranges the factors at different levels in accordance with their correlation and affiliation to form a multi-leveled analytical structure model, which ultimately boils the issue down to how to determine the relative important weights or priorities at the lowest level relative to the highest level.

(1) Establishment of hierarchical model
Complex issues are divided into so-called elements, which are divided into several groups according to their different properties and has formed different levels. Elements at the same level are taken as criteria to dominate certain elements at the next level. At the same time, they are dominated by elements at the previous level. The dominance between levels is not necessarily absolute. Namely, there can be such element that doesn't dominate all elements at the next level. The number of levels and complexity of issues have a relation to how detailed the analysis requires to be. There cannot be more than nine

factors at each level. A good hierarchical structure is extremely important for solving an issue.

Divide the goals of decision, considerations (decision criteria) and decision-making objects into top level, middle level and lowest level according to their relations, and draw a hierarchy chart.

Top level: the purpose of decision-making; issues to be solved.

Lowest level: decision alternatives.

Middle level: considerations; decision-making criteria.

For neighboring levels, the top one is called target level, and the lower one is called level of factors.

(2) Pairwise comparison constructed for judging matrix

After the establishment of the hierarchy, the affiliation is be determined between elements of upper and lower levels. Take an upper-level element A_k as a criterion, which dominates the next level's elements $B_1, B_2, \ldots, B_n$. Our aim is to give corresponding weights to $B_1, B_2, \ldots, B_n$ based on their relative importance under the criterion A_k.

If there are only qualitative results when determining the weights between factors at all levels, usually it is not easy to be accepted by others. Therefore, Saaty, et al. proposed the method of consistent matrix:

① Avoid putting all factors together and adopt the method of pairwise comparison.

② In order to improve accuracy, relative scale is used at this time to minimize the difficulty when factors of different nature are mutually compared.

Suppose there are n factors $x_1, x_2, x_3, \ldots, x_n$, whose importance to the decision-making (weights) are $v_1, v_2, v_3, \ldots, v_n$. Make a pairwise comparison between the importance of all factors, and their mutual relation can be represented by the following matrix:

$$\begin{bmatrix} v_1/v_1 & v_1/v_2 & v_1/v_n \\ v_2/v_1 & v_2/v_2 & v_2/v_n \\ v_n/v_1 & v_n/v_2 & v_n/v_n \end{bmatrix}$$

The matrix is called judgment matrix. It makes a pairwise comparison for the importance of certain factors at the same level (single hierarchical arrangement), and quantizes the relative importance of all factors through the approach of scaling.

Judgment matrix presents the relative importance of all factors at this level in comparison with a certain factor at the above level. For criterion A_k, which element is more important, B_i or B_j? How much more important? A certain value is required to be given to differentiate the importance. The element a_{ij} of judgment matrix is given by Saaty's approach of 1–9 scaling, which is a good way to quantize the judgment of thinking. When making a differentiation, people always use words like "the same", "greater", "much greater", "extremely greater". If further subdividing these levels, compromise wording can be inserted in two adjacent levels, so for most decision-makings, 1–9 scaling is adaptive, as shown in Table 1. As the scaling primarily reflects the quantitative value of interrelationship between qualitative indexes, its size of value is not important. The key point is whether the interrelationship of its values can accurately reflect people's judgment on the qualitative importance.

Table 1. Meaning of 1–9 scaling.

Scaling	Meaning
1	It represents that two factors have the same importance in comparison
3	It represents that one factor is a little more important compared to another factor
5	It represents that one factor is obviously more important compared to another factor
7	It represents that one factor is a highly more important compared to another factor
9	It represents that one factor is extremely more important compared to another factor

2, 4, 6 and 8 represents the median value of the above determination.

(3) Calculate relative weights of elements under single criterion

This step is to calculate the ranking weights of element $B_1, B_2, \ldots, B_n$ under the criterion A_k, and to check their consistency. For $B_1, B_2, \ldots, B_n$, judgment matrix X is obtained through pairwise comparison to solve the eigenvalue.

$XW = \lambda_{max} W$. By calculating the largest eigenvalue λ_{max} of judgment matrix, the obtained W adopts ranking weight under criterion C_k after normalized as element $B_1, B_2, \ldots, B_n$, where W is the corresponding feature vector, that is the importance (weight) vector $W = [w_1, w_2, w_3, \ldots w_n]^T$. This method is called as eigenvalue approach for calculating ranking weights. λ_{max} exists with uniqueness, and W may be composed of positive components. Except a lack of constant multiple, W is unique. The calculation of λ_{max} and W generally adopts the power method. If precision is not highly demanded, we can calculate λ_{max} and W through approximation methods, which mainly include sum method and root method. This paper applied the root method for calculation with main steps as follows: first, normalize the elements of X by the column; second, add the elements of A by the row; third, normalize the resulting rows and vectors to

obtain the ranking weight vector W; fourth, calculate λ_{max} in accordance with formula (1):

$$\lambda_{max}=\sum_{i=1}^{n}\frac{(XW)_i}{nW_i} \tag{1}$$

The $(XW)_i$ in Formula (1) represents the ith element of XW.

Eigenvalue method is the earliest approach proposed in *AHP* to calculate ranking weight vectors in wide use. When judging the matrix structure, consistency is not required due to the complexity of objects and the diversity of people's knowledge. But it's reasonable to require a general consistency in the judgment, so it normally violates our common sense if a case goes as: A is extremely more important than B, B is extremely more important than C, and C is extremely more important than A. Moreover, when the judgment deviates too much from consistency, there will be a problem if decisions are made on the calculation results of ranking weight vectors. So a consistency test is required after getting the λ_{max} by steps as follows:

$$C.I.=\frac{\lambda_{max}\text{-n}}{\text{n-1}} \tag{2}$$

Where n is the order of judgment matrix.

① Average random index $R.I.$ of consistency

Average random index of consistency is obtained by taking the arithmetic mean from repeated (500 times) calculation of random judgment matrix eigenvalues. Saaty's average random indexes of consistency are shown in Table 2.

② Calculate the consistency ratio $C.R.$

$$C.R.=\frac{C.I.}{R.I.} \tag{3}$$

When $C.R.$ <0.1, it is generally considered that the consistency of judgment matrix is acceptable.

(4) Calculate the combination weight of elements at all levels

In order to obtain the relative weight of all elements at each level in the hierarchy compared to the overall objective, we need to appropriately combine the results of the third step, and check the general consistency of the determination. This process is carried out in turn from the highest level to the lowest level. The end results involve the lowest level elements, the relative weight of decision priorities and the consistency checking on the judgment of the entire hierarchical model.

AHP's final result is the weight of decision priorities relative to the overall objective, and gives the overall consistency index of all judgments in the entire hierarchy, which is the foundation of the combination's ranking weight, and decisions can be made accordingly.

Table 2. Average random index of consistency.

Order n	1	2	3	4	5	6	7	8	9
R.I	0	0	0.58	0.90	1.12	1.24	1.32	1.41	1.45

3.1 *Hierarchical model of risk evaluation*

The factors inducing rock burst may act individually or work together, and the same region may be influenced by several different factors, which greatly increases the risk of rock burst in the region.

Establish a hierarchical model of evaluation system for rock burst hazards. For the problems concerning multivariate hierarchical analysis and evaluation on rock burst hazard, divide them into 5 levels, i.e., mining depth, coal structure, geological structure, spatial structure of overlying strata and that induced by coal pillar. Different properties are channeled to different groups at different levels, as shown in Fig. 2, and determine the

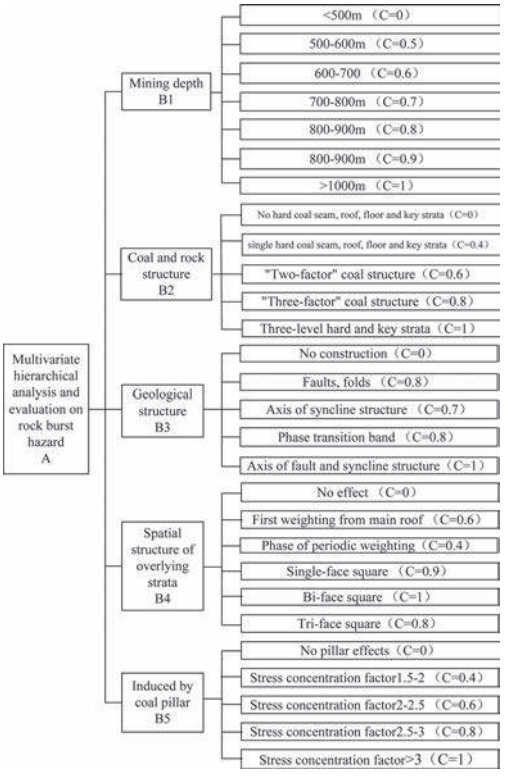

Figure 2. Rock burst hazard multivariate hierarchical model.

evaluation index. After getting the corresponding weight of evaluation indexes, calculate the risk index of burst hazard and determine the degree of risk. The region's risk index of rock burst hazard is the overall objective A. B_1, B_2, B_3, B_4 and B_5 respectively represent the mining depth, coal structure, geological structure, spatial structure of overlying strata and the quantized value of inducing factors of coal pillar. K_1, K_2, K_3, K_4 and K_5 respectively represent the mining depth, coal structure, geological structure, spatial structure of overlying strata and the weight of inducing factors of coal pillar. The relation between the overall objective A and B-level elements can be expressed by formula (4).

$$A = K_1B_1 + K_2B_2 + K_3B_3 + K_4B_4 + K_5B_5 \quad (4)$$

Based on the analysis on causes to rock burst hazards, the author made a thorough study in various factors, in order to give an empirical relationship for guiding on-site production.

(1) Construct a judgment matrix

Make a pairwise comparison for the above five levels of factors, construct a judgment matrix according to the 1–9 scaling, and the matrix is as follows:

$$\begin{bmatrix} 1 & 1/2 & 1/3 & 1/3 & 1/2 \\ 2 & 1 & 2 & 1/2 & 2 \\ 3 & 1/2 & 1 & 2 & 1/2 \\ 3 & 2 & 1/2 & 1 & 1/2 \\ 2 & 1/2 & 2 & 2 & 1 \end{bmatrix}$$

(2) Calculate the maximum eigenvalue and eigenvector

After calculation, the eigenvector of judgment matrix is W = [0.0844, 0.2543, 0.2022, 0.2140, 0.2451]^T, and the largest eigenvalue is $\lambda_{max} = 5.6035$.

(3) Consistency check

$C.R.$ = 0.065 <0.1, so the consistency of judgment matrix can be accepted.

The multivariate analytic hierarchy relationship of rock burst hazard is as follows:

$$A = 0.0844B_1 + 0.2543B_2 + 0.2022B_3 + 0.214B_4 + 0.2451B_5.$$

Finally, determine the degree of risk in a given region through Table 3.

Considering the complexity of rock burst, the above formula of general experience can basically be applied to most mining cases, but in specific conditions, it should be analyzed based on the actual situation, in order to re-construct the judgment matrix and have a consistency checking and determine the multivariate hierarchical relationship of rock burst hazard.

Table 3. Comparison table for risk factors and the degree of risk.

Risk factor	$A < 0.33$	$0.33 \le A < 0.66$	$A \ge 0.66$
Degree of risk	General risk area	Moderate risk area	High-risk area

4 ENGINEERING APPLICATIONS

Since 2003, several serious rock bursts have occurred in Jisan Coal Mine during extraction. Hundreds of meters of roadway were destroyed, and dozens of single props were damaged, posing a big threat to mining safety.

Working Face No. 5305 is Shanxi formation coal seam No. 3 with thickness of 1.2 ~ 3.6 m. The working face is westward adjacent to the goaf of working Face 5306, and eastward adjacent to the goaf of Face No.5304. It belongs to island face, with a mining depth of 615 ~ 702 m but without immediate roof. The main roof is in fine sandstone and siltstone, strong and stable, with a thickness of 13.57 ~ 25.49 m. The overall trend of the coal bed shows a relived syncline, which is high in the north and south and low in the middle. Most faults are developed in the south wing of the syncline, with a main of direction of SE or SEE. Revealing faults according to the actual situation, it is expected to expose 15 faults with a fall of 1.3 ~ 4.6 m. Working Face No.5304 is a skip-mining face, and a coal pillar of 200 m long is left in the centre of face. The tendency of coal seam No.3 and rock burst is identified as weak shock. For "island" faces with complex mining environment, an evaluation on rock burst hazard before mining is needed in order to take preventive measures in advance.

4.1 *Analysis on influencing factors*

First, apply the theory of strata movement and underground pressure, combine with the mining conditions of Face No. 5305, and determine the influencing factors of rock burst. Second, adopt methods such stress analysis, evaluation on rock pressure and geological structure and engineering analogy to assess potential risk zones.

(1) Evaluation on the relation between mining depth and rock burst hazard

Working Face No. 5305 has an average mining depth of 658 m, which exceeds the critical depth of incurring a rock burst, so its depth meets the condition.

(2) Evaluation on the relation between coal structure and rock burst hazard

Make an analysis on the distribution of critical rock stratum that induces burst hazard and its relationship with the location of coal seam: About 20 m above the main roof of coal seam, there is fine sand strata with a thickness of 9.76 ~ 21.65 m. The presence of this hard roof will aggravate the stress concentration of working face, crossheading and area near the pillar. It is a crucial stratum for inducing rock burst.

There is extremely thick and hard stratum of red medium-sand, 132.2 ~ 186.3 m away from the roof of coal seam No.3. The key stratum may induce mine earthquake if disturbed. Since the stratum is far from the earth's surface (about 340 m), there won't be direct impact on the earth's surface during a mine earthquake. This stratum is also critical for inducing rock burst.

(3) Evaluation of engineering analogy on the relation between geological structure and rock burst

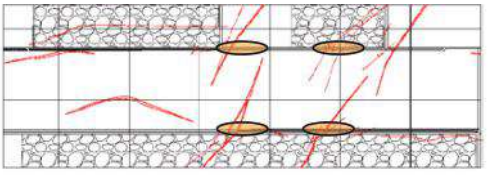
Geological structure is one of the factors inducing rock burst. Stress can locally concentrate in the axis of the syncline and in the vicinity of faults, thereby inducing rock burst.

The coal stratum of Face No.5305 has an overall trend of a relived syncline, which is high in the north and south and low in the middle, and there is large tectonic stress near the axis. The fault is in the vicinity of synclinal axis, indicating that the tectonic stress is strong in the premise, so the geological structure (relived syncline and fault) has a possibility of inducing rock burst.

The rock burst happened in the mine's working Face No.6303 and No.6304 was caused by geological structure. See Table 4 for an engineering analogy on the geological structure of three faces.

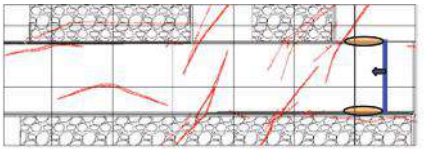
According to the engineering analogy of geological structure, it is determined that rock burst may occur in the working face, which is a risk zone to induce rock burst since it is affected by geological structure, see Fig. 3 (a).

Table 4. Engineering analogy for rock burst induced by geological structure.



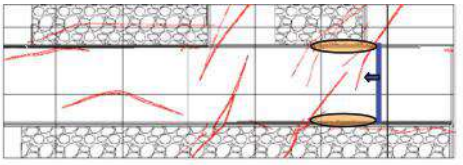
Working face	Syncline	Axis fault	Oblique fault, goaf	Extent of burst
6303	Yes	Yes	No	Rock burst occurs.
6304	No	No	Yes	Strong vibration in coal wall and roof, stop mining to deal with it.
5305	Yes	Yes	Yes	Ground pressure may occur.

(4) Evaluation on the relationship between the movement of the spatial structure of overlying strata and dynamic disasters (rock burst and mine earthquake)

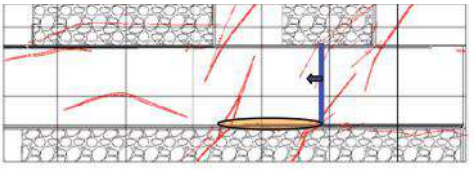


With the advance of working face, the spatial structure of overlying strata will gradually form the shape of "S" and "C". If stress is aggregated to a concentration, it may induce rock dynamic disasters (rock burst and mine earthquake).

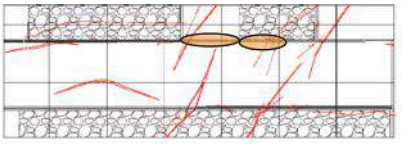
① Initial fracture of main roof



With the recovery of working face, the first weighting step of main roof is about 60 m according to mining experience of the mine. Taking a comprehensive



(a) Geological structure and risk zone of rock burst



(b) First weighting of main roof and risk zone of rock burst

(c) Square of working face and risk zone of rock burst

(d) Square of double face and risk zone of rock burst

(f) Hazardous zone of rock burst affected by C-shape structure of overlying strata

Figure 3. Multi-factor-induced burst danger zone.

consideration on the impact of faults, the risk zone is identified as shown in Fig 2 (b).

② Square of working face

When the recovery of working face reaches about 220 m with a range of 200 ~ 230 m, it goes into the phase of face square. Taking a comprehensive consideration on the impact of two faults nearby, the risk zone is identified as shown in Fig 2 (c).

③ Square of double face and impact of three faces

There is extremely thick and hard stratum of reddish-brown fine-grained sandstone above the coal seam, and it is a critical stratum affecting the recovery of working face. When face recovery reaches from 200 m to 450 m and forms double-face square with Face 5306, the act of mining may have an impact on the upper hard-thick strata.

In the process of mining, evaluation of numerical simulation is adopted in order to study the changes of stress, the fracture damage, and the possibility of inducing mining earthquake or rock burst. Establish a three-dimensional numerical model, the top of which is 331 m vertically away from the ground. Through simulation, the hard roof might have certain impact on the coal wall of working face in the process of recovery. The thick and hard critical stratum may be disturbed, and the hard-thick strata in the overlying stratum of coal seam may suffer from a fracture, so there is a possibility of instability, which induces mining earthquake. A large amount of elastic energy will be released in the process of rock fracture, and it can easily lead to mining earthquake or rock burst. As it is far away from the ground, there won't be an impact on the earth's surface, but there is a possibility of mining earthquake inducing rock burst in front of the working face. According to the numerical simulation results, the scope affected by the fracture of thick and hard critical stratum and main roof ranges 350 ~ 435 m from the open-off cut, and the risk zone in this phase is identified as shown in Fig. 3 (d).

(4) Phase of periodic weighting

After the periodic weighting of main roof, risk will rise in the hazardous zone within a scope of 70 ~ 100 m in front of the working face. When working face pushes through the area of coal pillar, the risk of burst for the face is mainly affected by the structure of "C"-shape overlying stratum. According to the movement of "C"-shape overlying strata, the risk zone is identified as shown in Fig. 3 (e).

(5) Evaluation on rock burst induced by coal pillar

The coal pillar left in the centre of adjacent skip-mining Face No. 5304 may lead to local stress concentration and an accumulation of a large amount of elastic energy, so there is a risk of rock burst.

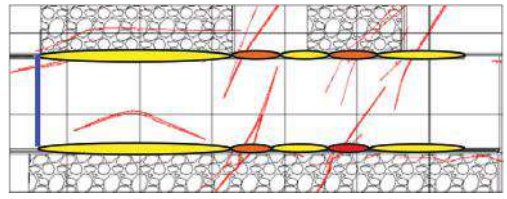


Figure 5. Risk zone of burst determined by multivariate analytic hierarchical evaluation.

Evaluate the risk of rock burst induced by coal pillar though engineering analogy. In Sep. 9, 2006, the boring head of Face No. 1410 in Huafeng Coal Mine induced rock burst and caused great damages and casualties. Microseismic monitoring displayed a mine earthquake magnitude of 2.0 and energy of 2.2×10^7 J.

In a range of 380 ~ 730 m from the open-off cut, Face No. 5305 is threatened by the rock burst which may be induced by coal pillar. Based on the above analysis, the mining height of Face No. 5305 is small, and there is fully mechanized coal mining on one side of full-height at a time. It is unlikely to have burst of high intensity, but there is still a possibility. Face No. 5305 has strong shear zone in both sides of the coal pillar, and the risk zone is shown in Fig. 3(f).

(6) Multivariate analytic hierarchical evaluation on the risk of rock burst and the determination of risk zones

According to the multivariate evaluation on the risk of rock burst, these areas are divide into three categories: 6 general risk zones (yellow), 3 moderate risk zones (orange), 1 high-risk zone (red), as shown in Fig. 5.

5 CONCLUSIONS

1. Areas with different degrees of risk are determined according to the multivariate hierarchical evaluation on the risk of rock burst in working face. The method focuses on specific conditions and has a dynamic and integrated feature. Since some of the indexes depend on experience, it belongs to semi-quantitative evaluation method that can more accurately determine the risk of hazardous area.
2. By means of numerical simulation, in double face square, the hard-thick strata above the coal seam may be affected by the mining area and have mining earthquake induced by the hard-thick strata. It won't produce disastrous effects to the ground, but may lead to a sharp concentration of coal seam stress, which may induce burst.

3. Based on the evaluation results, take the principle of "pressure relief before mining" for risk zones in advance. Design for pressure relief according to the degree of risk during construction while checking the stress in process of mining to ensure that measures are in place for getting rid of danger and playing a relief effect.

ABSTRACT: To study the dangerous of rock burst induced by instability of key strata overlying, the stability of longwall mining face need to be investigated before mining. Taking thick-hard key strata of overlying mining face No. 5305 in Jinsan Coal Mine for example, the stability of numerical simulation for mining was performed. The results showed that the height of roof strata rupture to the key strata beneath when the face advancing 350 m; distribution of plastic zone along strike and dip direction indicated key strata failure, when face advancing 435 m, the dangerous distance of rock burst impacted by failure of key strata is 350 ~ 435 m away from open-off cut. It is practiced that, while the face advancing to this area, mine earthquake was reduced by the thick key strata failure, so there is no induced burst, due to take stress relief in advance. Prevention goal of mine earthquake without disaster is realized.

1 INTRODUCTION

Rock burst is one of the serious disasters in coal mine exploiting. With the increment of exploiting depth in China, more and more coal mines are threatened by rock burst and mine earthquake which occur more and more frequently. It leads to seriously properties losing and casualties. Key Strata Theory (Qian M, et al. 1996), which is better application for gas extraction, surface subsidence, water inrush, underground pressure control and rock burst prevention (Xu J & Qian M. 2000; Qu Q, Xu J & Qian M. 2007; Zhu W, et al. 2009; Xu J & Ju J. 2011; Xu J, Chen J, Jiang K. 2007; Cheng Y, et al. 2006), was presented by Qian. The instability of key strata is one of the main factors induced rock burst, and there is a close relationship between the instability of key strata and rock burst. Therefore, the possibility of rock burst induced by the instability of key strata should be investigated before mining to take stress relief measures in advance. In terms of risk evaluation of rock burst, many researchers have presented different evaluation methods. Bayesian discriminant analysis is used for predicting coal and gas outbursts (WANG C, et al. 2010). A coupled artificial neural network and fault tree analysis model to predict coal and gas outbursts is presented (Zhang R L & LOWNDES I S. 2010). The catastrophe progression method in predicting coal and gas outburst is presented (Zhang T J, et al. 2009).

This paper is based on the numerical simulation, to study the stability of thick-hard key stratum.

2 BACKGROUND

Jinsan Coal Mine is one of China's oversize mines. Since 2003, serious coal rock behavior is occurred repeatedly during the mining period, hundreds of meters tunnel is destroyed, and dozens of props are damaged. A great threat is brought to the coal mine production safety.

Working Face No. 5305 is Shanxi formation coal 3 with seam thickness of 1.2 ~ 3.6 m. The working face is westward adjacent to the goaf of working Face No. 5306, and eastward adjacent to the goaf of Face No. 5304. It belongs to island face, with a mining depth of 615 ~ 702 m but without immediate roof. The main roof is in fine sandstone and siltstone, strong and stable, with a thickness of 13.57 ~ 25.49 m. The overall trend of the coal bed shows a relived syncline, which is high in the north and south and low in the middle. Most faults are developed in the south wing of the syncline, with a main of direction of SE or SEE. Revealing faults according to the actual situation, it is expected to expose 15 faults with a fall of 1.3 ~ 4.6 m. Work-

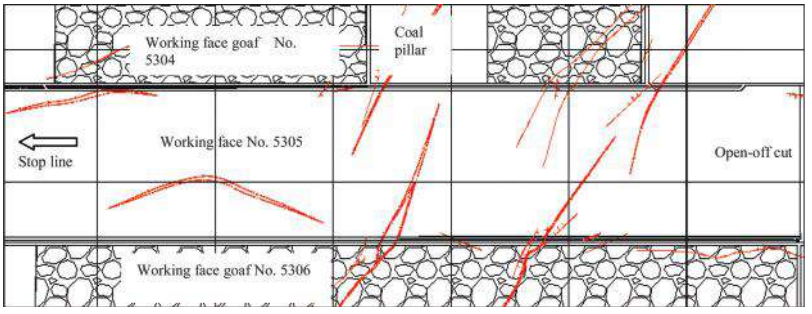

Figure 1. The plan view of the working face No. 5305.

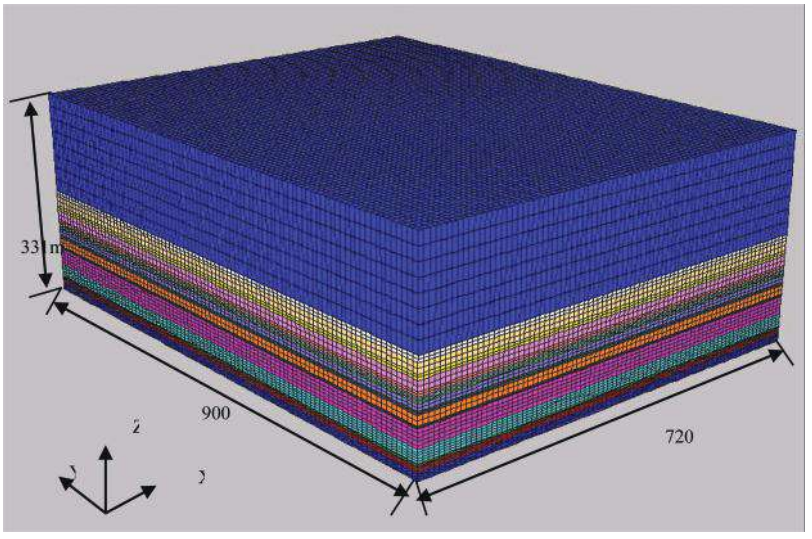

Figure 2. 3-Dimensionalnumerical model.

ing Face No. 5304 is a skip-mining face, and a coal pillar of 200 m long is left in the center of face. The tendency of 3 coal and rock burst is identified as weak shock. For "island" faces with complex mining environment, an evaluation on rock burst induced by key stratum instability before mining is needed in order to take preventive measures in advance.

3 NUMERICAL MODELING AND ANALYSIS OF RESULTS

3.1 *Setting up of the numerical model*

In this paper, FLAC^{3D} has been used to simulate the stability of the hard-thick key stratum. Fig. 2 shows the three-dimensional numerical model established, and the top boundary of the model is located approximately at a depth of 330 m. The dimension of the model is 720 m × 900 m × 331 m. Roller boundaries are placed at four boundaries of the model except at the top and bottom boundary. The boundaries are "fixed" only in a specified direction (i.e., no displacement or velocity is allowed). Lateral boundaries cannot move in the horizontal direction. The fixed bottom boundary cannot move in the vertical direction. A vertical stress of 8.2 MPa (*zz*-stress) was applied at the top boundary of the model. Fig. 3 shows the boundary conditions of the numerical model.

3.2 *failure criterion*

FLAC has several built-in material behavior models. The failure of rock material is assumed to follow the Mohr–Coulomb criterion as illustrated in Fig. 4 which is used for materials that yield when

subjected to shear loading, but the yield stress depends on the major and minor principal stresses only; the inter mediate principal stress is assumed to have no effect on yield.

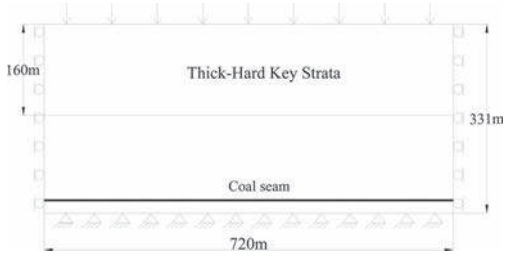

Figure 3. Boundary conditions of the numerical model.

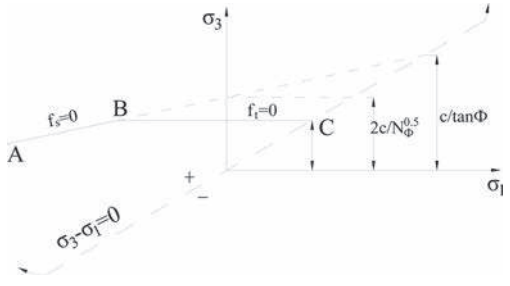

Figure 4. Mohr-Coulomb failure criterion (FLAC3D 2002).

The failure envelope $f(\sigma_1, \sigma_3) = 0$ is defined from point *A* to *B* by the Mohr-Coulomb failure criterion $f_s = 0$ with

$$f_s = \sigma_1 - \sigma_3 N_\varphi + 2c\sqrt{N_\varphi} \quad (1)$$

and from B to C by a tension failure criterion of the form $f_t = 0$ with

$$f_t = \sigma_3 - \sigma_t \quad (2)$$

Where ϕ is the friction angle, *c,* the cohesion, σ_t the tensile strength, and

$$N_\varphi = \frac{1+\sin\varphi}{1-\sin\phi} \quad (3)$$

3.3 *Physical and mechanical properties of coal and rock*

The layer sequence and the thickness of each layer used in the model are given in Table 1. Physical and mechanical properties selected to represent the coal and rock masses and to perform stress-deformation analysis are also shown in Table 1. The values selected to represent Young's Modulus, cohesion and tensile strength is about 30% less than the intact rock values. The value used to represent Poisson's ratio is about 20% higher than the intact rock value. Therefore, the selected mechanical property values represent the equivalent continuum properties of each rock mass.

Table 1. Physical and mechanical property values used for rock and coal masses in the numerical model.

Layer sequence from top to bottom	Thickness (m)	Density (kg/m^3)	Bulk modulus (GPa)	Shear modulus (GPa)	Cohesion (MPa)	Internal friction angle (°)	Tensile strength (MPa)

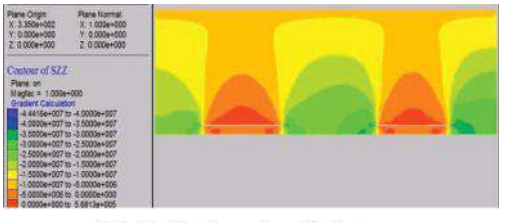
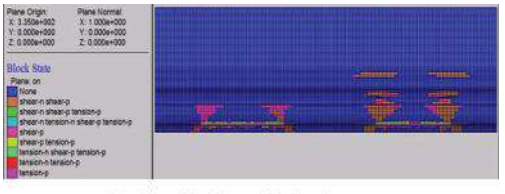
4 ANALYSIS OF RESULTS



The model built was calculated to equilibrium, and the stress status of the key stratum was initialed. Then stoping the working face No. 5304 and No. 5306, respectively, the stress status of the key stratum was monitored to determine the disturbed situation of the key stratum. Finally, the stoping of working face No. 5305 was simulated to analyze the instability of key stratum and the possibility of mining earthquake.

After the longwall face No. 5304 and No. 5306 were mined out, the distribution of vertical stress is illustrated in Fig 5(a), the stress status of the key stratum is changed a little and the scale of stress value is 5–15 MPa; the distribution of plastic zones is illustrated in Fig 5(b), and the statue of the key stratum is intact. Therefore, the key stratum is stable judged by the distribution of vertical stress and plastic zones.



When the 5305 face was advancing 250 m, 300 m, 350 m, 400 m respectively, the failure height of the overburden strata above coal seam is increasing, according to the distributions of plastic zones shown in Fig. 6. When the face was advancing 350 m, the failure height of the overburden strata reaches to the underneath of the key stratum. When the face was advancing 400 m, the key stratum is starting to fracture, as shown in Fig. 6(d) and Fig. 7. At this point, there is the risk of rock burst induced by mine earthquake, if the key stratum is fractured. While the face was advancing 435 m, the key stratum has fractured mainly, as shown in Fig. 8; the risk of rock burst induced by mine earthquake is reduced. Consequently, the most dangerous area is the scope of 400 m~435 m away from open-off cut.

According to the numerical simulation results, the scope affected by the fracture of thick and hard critical stratum and main roof ranges 350 ~ 435 m from the open-off cut.

When the longwall mining face was advanced at the distance 410 m from open-off cut, the hard-

thick key stratum was fractured and induced mine earthquake. The prevention measures of stress relief were applied in advance, simultaneously, the monitoring and pre-warming methods was used. Finally, there is no rock burst induced in this working face.

5 CONCLUSIONS

It is practiced that, when the longwall mining face was advanced at the distance 410 m from open-off cut, the hard-thick key stratum was fractured and induced mine earthquake. Due to the prevention measures of stress relief in this area underneath the key stratum in advance, there is no coal burst in the working face. The method of numerical simulation is suitable for investigating the possibility and influenced zones of rock burst and mine earthquake induced by the instability of the key strata.

Research on the free radical affecting methane outburst within coal under the electromagnetic radiation

M. Shang-Quan & F. Jing
North China Institute of Science and Technology, Beijing, China

ABSTRACT: Currently coal and methane outburst disasters still remain seriously. This article aims at looking for the source of methane from the microscopic molecular structure of coal. chemical changes and particle interactions in chemical changes of coal and methane outburst during the impact are theoretically analyzed and a set of electromagnetic radiation experimental scheme is set to research the possibility of fracture and bond of CH_3–, CH_2 = CH– and H– and creating new methane. The basic theory of seam methane disaster prevention through the experiment is innovated.

1 INTRODUCTION

In China, there are more than 55% of key state-owned coal mines with high methane outburst. Although in recent years, coal mine methane has been effectively controlled, the major methane outburst accidents still occurred now and then. The complex process mechanism of coal and rock dynamic disasters has not yet been fundamentally solved and the prevention is a worldwide problem. For a long time, lots of researches using mechanics approach from a macro perspective on mine coal and methane outburst mechanism have been done. Most researchers believe that the outburst phenomenon is caused by the combination of three factors, which are stress, methane pressure and structural properties of coal, and also the high-speed release is caused by the potential of coal body, including of elastic energy, methane potential in the surrounding rock and coal. The mechanism of explanation about the role of the organic macromolecular structure of coal and chemical properties of free radicals is not generally accepted. My experiment shows that a radical change in the coal has played an important role in the process of methane outburst, which should be experimented.

2 RESEARCH STATUS

The observations and researches of rock fracture electromagnetic radiation (EME) were carried out earlier in China and the former Soviet Union. In 1953 Guevara Pavlovic, Pal Mainbranch(GUEVARA 1954) experimentally recorded and studied granite, gneiss and quartz piezoelectric phenomenon and the light emission. American scholar Nitson(NITSON 1977) and Chinese scholar Xu Weimin(XU 1985) also reported laboratory findings of the piezoelectric effect of rock. Shefrin Zoff(SHEFRIN 1975) studied the effect of feldspar stepanov, experimentally found that under a uniaxial deformation with the speed of 0.2 mm/s, the surface density of the sample was 10^{-5}~10^{-9}C/m^2 charge. Sun Zhengjiang(SUN 1985) recorded electromagnetic radiation signal when loaded on diorite, marble, limestone, and when the main rupture happened, according to the magnetic field strength, he calculated the fracture surface charge was 5.2×10^{-4}C, the surface charge density is 1.4×10^{-2}C/m^2. He Xueqiu and Liu Mingju's studies have shown(HE 1995) that, for the first time through experiment, there are electromagnetic radiation generating during the process of deformation and failure of coal. Wang Enyuan, He Xueqiu, Nie Baisheng(WANG 2005, WANG 2003) studied the spectrum of electromagnetic radiation and variation of coal and rock containing methane, found out that the deformation and fracture of coal and rock and electromagnetic radiation are closely related. Coal contains large amounts of free radicals, Feng Shian(FENG 1998) found that tectonic coal and its adjacent non-deformed coal compared to radical concentration is not the same, radical concentration is regarded as coal methane outburst dangerous area predictors. Tang Xiuyi(ZHANG 1997) measured radical concentration in coal mines in Huainan, Huaibei outburst and non-outburst, the former was doubled more than the latter. Guo Deyong(GUO 1999), after the study of tectonic coal ESR spectra, also supported the use of radical concentration as coal and methane outburst prediction of a zoning indicator.

On the whole, the study on mechanism of coal and methane outburst has made significant progress in china and abroad. However, owing to the physical and mechanical properties of coal nonlinear, rock damage in the form of methane occurrence and migration diversity and complexity of the process, the cause is not very clear. Thus, a theoretical and experimental theoretical system has not been formed and no definite experimental result can reveal the mechanism of coal and methane outburst.

3 COAL STRUCTURE AND RADICAL RESEARCH

The main structure of coal is amorphous polymers. Each coal molecule is composed of a number of the basic structural unit with similar but not exactly the same structure (HALL 1994). The basic structural unit of the core is mainly condensed aromatic ring, and a few hydrogenated aromatic, alicyclic and heterocyclic. The complete molecular structure of the coal comprises two parts: more stable performance, with a solid, not a chemical reaction of the core (aromatic nucleus) and surrounding the nucleus and a variety of side chain functional groups. Oxygen-containing functional groups are the major part of the functional group, including light phenol group, a carboxyl group, a methoxy group, and the carbon group, and also a small number of sulfur-containing functional group and nitrogen-containing functional groups. The basic structure units are connected with each other via a bridge to form the coal macromolecule. Coal molecules can form different three-dimensional structure through intermolecular cross-linking and wound around the space.

Because of amorphous, highly complex and heteroge-neous structures of coal, it is still controversial about the chemical structure of the coal. Nevertheless, some of the structural model has been widespread concerned, such as Fuchs Model, Given Model, Wiser Model, Honda Model, Shinn Model etc. Wiser Model is considered to be more comprehensive reasonable model, shown in Figure 1.

It is not definite about how big the coal Molecules is. The basic structural units can be considered broadly in the range of 200 to 400, and the relative molecular weight is in the range of thousands (YE 2008). In the coal polymer structure is also more evenly distributed small amounts of small molecules (≤500amu). Zhang Yugui (ZHANG 2003) thinks the small molecule compounds in coal, although the number is not much, has a great influence on the nature of the coal. Hydrocarbons in the coal are mainly n-alkanes. Hydrocarbon

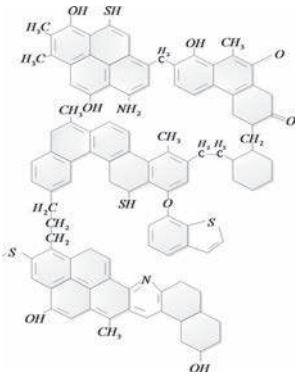

Figure 1. Wiser Model (YE 2008).

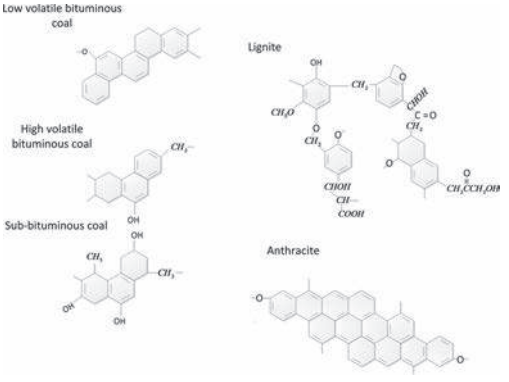

Figure 2. The basic structural unit of five kinds of coal diagram (TAO 1984).

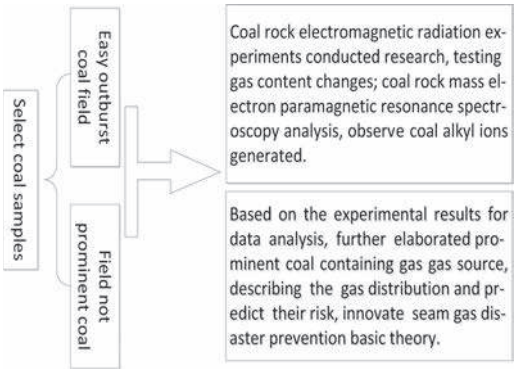

distribution is very wide, from the above C_1-C_3, and C_7 even found in reports(FANG 1996, FANG 1997), in addition to a small number of cycloalkanes, long chain olefins and 1–6 ring aromatic hydrocarbons (with 1–2 ring based) and so on. Between the C_{23}-C_{33}, coal intermolecular forces, charge transfer forces, π-π interactions, hydrogen bonding, van der Waals forces etc exist between ions. The bridge bond is quite common in the low rank coals which consists mainly of three kinds which are methylenebond(-CH_2-, -CH_2-CH_2-, -CH_2-CH_2-CH_2-, etc.), thioether bond, an ether bond (-0-, -S-, -SS-, etc.) and methylene ether bond (-CH_2-O-, -CH_2-S-, etc.), especially methylene ether bond. Moderate degree of coalification has the minimum number of coal bridges, mainly in the form-CH_2-and-O-, and to anthracite phase bridges increased again, primarily Car-Car, Figure 2.

Prediction: facing the problems of inconsistency during the process of the release of excess methane, methane composition and coal seam methane, could we find the source of the methane by taking it from projecting the microscopic molecular

structure of coal? Under the action of electromagnetic radiation, coal macromolecular structure has changed, part alkyl (CH_3-, CH_2 = CH-) and hydrogen (H-) molecules fractured from the coal. The reaction forms a new methane (CH_4) or methane and let the methane-containing coal and rock along with the stress gradient to rupture.

4 SUMMARY OF THE EXPERIMENTAL PROGRAM PREDICTION

A. Experimental General Idea

B. Experimental Methods

Subjects: The original state coal (block), crushing coal, after pumping through the methane exhaust methane of the coal.

Experimental environment: Keep coal in the underground with ambient pressure and temperature environments.

Experimental apparatus: Electromagnetic emission source, electromagnetic energy meter (tesla), high frequency mechanical wave recorder, coal and rock strain recorder, methane, ethane, carbon monoxide sensors, data logger.

Experimental principle: Figure 3

a. electromagnetic excitation b. gauge c. methane receiving container (sealed) d. methane test container (built methane, ethane, carbon monoxide sensors, not sealed) e. sealed container f. valve g. grating strain sensors h. Light vibration receiver i. data logger

Experiment: Excitation of electromagnetic waves, while recording non-excited state and the excited state changes of various physical quantities of data and curves.

(1)Fixed electromagnetic energy, and change the frequency of the electromagnetic wave. The Experiment tests the electromagnetic frequency characteristics of coal and rock.

(2)Fixed frequency of electromagnetic wave, and change the electromagnetic energy. The experiment

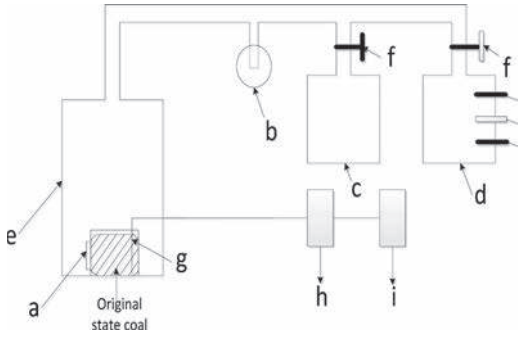

Figure 3. Electromagnetic waves schematics coal testing laboratory.

tests coal and rock under the action of the electromagnetic energy characteristics

Note: The experiment can be divided into two parts: The first step is to collect the methane, open the methane container valve, close the test container valve, store methane samples and analyze methane components with a spectrum analyzer. The second step is to close and collect the methane container valve, open the container valve inspection, inspect methane under the action of the electromagnetic state of change.

C. Experimental Targets:

1) According to the analysis of coal methane source from coal rocks, except coal and adsorption of free methane, is there a source of methane or methane product?

2) According to the theoretical analysis of coal different methane outburst effect, the methane outburst prevention theory and technology are innovated.

5 CONCLUSIONS

In summary, under the action of the external environment, coal containing methane has many effects, including optical radiation of electronic band mechanism, friction effect, piezoelectric effect, electromagnetic effect and so on. These experiments can test whether the expected effects make the coal macromolecular structure changed or not, such as Part alkyl (CH_3-, CH_2 = CH-) and hydrogen (H-) from the coal macromolecular fracture and whether form a new methane (CH_4) or methane. This experiment can provide strong arguments to analyze the different impact of methane during the process of coal containing methane. Under the premise of further exploring different methane outburst source, the prevention technology can be developed.

ABSTRACT: This paper studies on machine safety monitoring system of coal mine to tackle the problem of prevention of mechanical hazards protection, electrical safety and warning, Transport protection and so on. The system overall design includes three layers of controlling, information and equipment (Qiao et al. 2008). With the actual situation of a coal mine electrical and mechanical equipment monitoring and protection, respectively on the key technology of CAN-BUS, digital signal processing, distributed computing, database selection of in-depth research, after several trials in the north wing of central substation and a mine central pump house, the system run effect obviously in the aspect of safety, reliability and compatibility.

1 INTRODUCTION

Along with the construction of mechanization, coal mine production scale, large power equipment put into use, put forward new requirements for safe operation of coal mine power grid (Zhao 2011). After investigation, found that domestic coal transportation, ventilation general aimed to enhance the water supply equipment safety protection; electrical power equipment, leakage protection, short-circuit and overload has done a lot of work, but the machine protection each orphan, fault in coal mine power grid has randomicity and contingency, is not conducive to the power grid state (Mu et al. 2008), the mechanical operation of remote monitoring. To solve this problem, combined with the status of a mine safety system, early warning and protection system design, reasonable selection of new technology, perfect function, reduce the machine maintenance, improve the fault judgment, to ensure that the location and the cause of the accident to understand, identify signs of measures, reduce the failure effect, improve the safety production of the coal mine electrical and mechanical equipment the level of safety management.

2 SYSTEM DESIGN

The overall design of the system is divided into three layers, including the control layer, the information layer and the equipment layer:

1. The control layer: through the core switch and the ground control center with Ethernet interface CAN-LAN substation and industrial Ethernet switching device is connected, through the establishment of underground double fiber ring of high-speed information channel (Qiao et al. 2008) (using the TCP/UDP protocol, 100Mbps/10 Mbps adaptive transmission rate, transmission distance is less than 40(km), BER < 10–80).
   Ground center station by two Gigabit redundant Ring net switches, the two database server, a communication server, consisting of three industrial computers and other equipment, guarantee the safety of data transmission, stability. And equipped with display system, display the monitoring of network information. Equipped with UP uninterruptible power supply and redundant power supply, ensure the acquisition data of underground monitoring node of 24 hours of uninterrupted.
2. Information layer: the information of monitoring data processing, transfer, backup and analysis, discarding unnecessary data. Release function through data, all the monitoring node data released to bureau-level LAN (Deng & Wei 2007), in the LAN users authorized permission, real-time status monitoring nodes, view the real-time data, the query of historical data, alarm record monitoring.
3. Equipment layer: it is divided into the ground monitoring network and the underground

monitoring network. The ground monitoring network is mainly used for industrial bus, through the monitoring device, high-low voltage switch tank Protection Device. And the output of various kinds of report information. Cabinet protection device will ground information through the network access server industrial Gigabit self-healing ring network switch. The underground monitoring network mainly uses CAN bus, data acquisition device is connected with the CAN-BUS field bus and underground communication station.

3 KEY TECHNOLOGY

3.1 *Data bus technology*

Data bus technology CAN (Controller Area Network) is the most widely used, which is characterized by (1) Constitute a host system, CAN uses the main competitive bus structure, with multiple master operation and serial bus distributed arbitration and broadcast communication features. The network can take the initiative to send messages to other nodes on the bus nodes. (2) Stronger anti-interference ability. Only 2 wires connected with external and internal integration, error detection and management module, when the error occurs when a node of CAN bus, automatically close the node output function, and cut off the connection between nodes, so that other nodes are not affected. (3) Adopt non-destroyed bus arbitration technique. When multiple nodes initiate communication at the same time, avoid priority low priority high, while the node with the highest priority can be not affected continue to transmit data, save the bus conflict arbitration time. (4) Data transmitting with low bit errors ratio, CRC checksum test measures. Using CAN bus short frame structure, each frame of information containing 8B, short transmission time.

3.2 *Digital signal processing*

Technology of DSP digital signal processing (The digital signal process) has strong flexibility (Li et al. 2007). Its characteristics are

1. High degree of integration, integration of the chip is tens of millions of orders of magnitude.
2. High speed, its chip processing speed reached hundreds of megabytes of magnitude.
3. High current and low voltage, high speed signal processing chip current above 1 A. In order to reduce the power consumption of the system adopts low voltage.
4. Using a variety of parallel architectures. Because the digital circuit adopts two value logic, as long as the change of environmental temperature, circuit noise does not cause the circuit logic inversion, digital circuits are not affected by complete. Therefore, the application of digital signal processing technology has good stability.

3.3 *Distributed computing technology*

Application of distributed computing technology (DC:Distributed Computation), the system is divided into the main computer system and monitoring station computer system control center. It is characterized by distributed computing can load calculation on multiple computers balance. The program, the data processed by the program and the actual computation tasks are distributed in the network, processing ability to regulate multiple computers, characteristics and application is composed of different modules (Shao et al. 2007).

3.4 *Real-time database technology*

Real-time database RTDB (Real-Time Database) is the combination of database and real-time technology (Liu & Yao 2005). Is characterized by:

1. Collection, processing, storage and real-time data in the whole system,
2. It is responsible for the history data statistics, analysis, alarm, query and other requirements.
3. It is responsible for the underground monitoring collected data processing and storage, communication between the database and server.
4. It is responsible for the data processing and analysis by the network is displayed to the user, so the real-time database and provide basic data and basic information for monitoring system, is the foundation of realizing the whole safety coal mine electrical network real-time monitoring and warning function.

4 SYSTEM FEATURES

4.1 *System function*

Monitoring system of coal mine electromechanical equipment and high and low voltage power grid real-time data acquisition, transmission of information, record data, online monitoring. The technique involves industrial Ethernet, field bus, embedded software, digital signal processing, distributed computing, real-time database, configuration software, network integration technology (Liu & Yao 2005, Deng & Wei 2007).

The monitoring system, the database server is first transferred to the system hardware configuration table and data dictionary, loading hardware

drivers, generating equipment monitoring and real-time database, and according to the timing acquisition hardware configuration data; when the monitoring workstations are identified, through the database server load monitoring interface configuration file generation monitoring interface of the control system, and generates a mapping system all real-time monitoring data, and then the server and workstation continuous exchange of real-time data (Li et al. 2007), realize the process of monitoring system.

4.2 *System structure*

System between the high-speed transmission data through the real-time database, network and the seamless connection. The system has real-time monitoring, electrical protection, fault warning, integrated query and system management function.

The system structure as shown in Figure1.

4.3 *System performance*

Resource sharing: system provides the connection open data, avoid coal mine power network subsystems independent operation monitoring island formation.

Safety: the system CAN bus for data transmission and automatic control between the underground monitoring equipment (Mu et al. 2008), realize the connection between the field bus and the ground control center by downhole LAN.

System compatibility: the implementation of international standards, is open, convenient for other systems connected; to consider the use of domestic main stream equipment, use of existing equipment, saving investment.

Scalability: the underground monitoring equipment and communication equipment using the embedded system software and communication software, flexible configuration, convenient installation, so as to the future of the system expansion and upgrade.

5 EFFECT OF PRACTICE

5.1 *Operation practice*

This system is put into use in a certain mine north wing of central substation and a central pump house, and achieved good effect and economic benefit of society. Practice shows that the system design is reasonable, stable and reliable operation, and the operation is simple and convenient. The system is able to achieve accurate monitoring, equipment operation data, provide the basis.

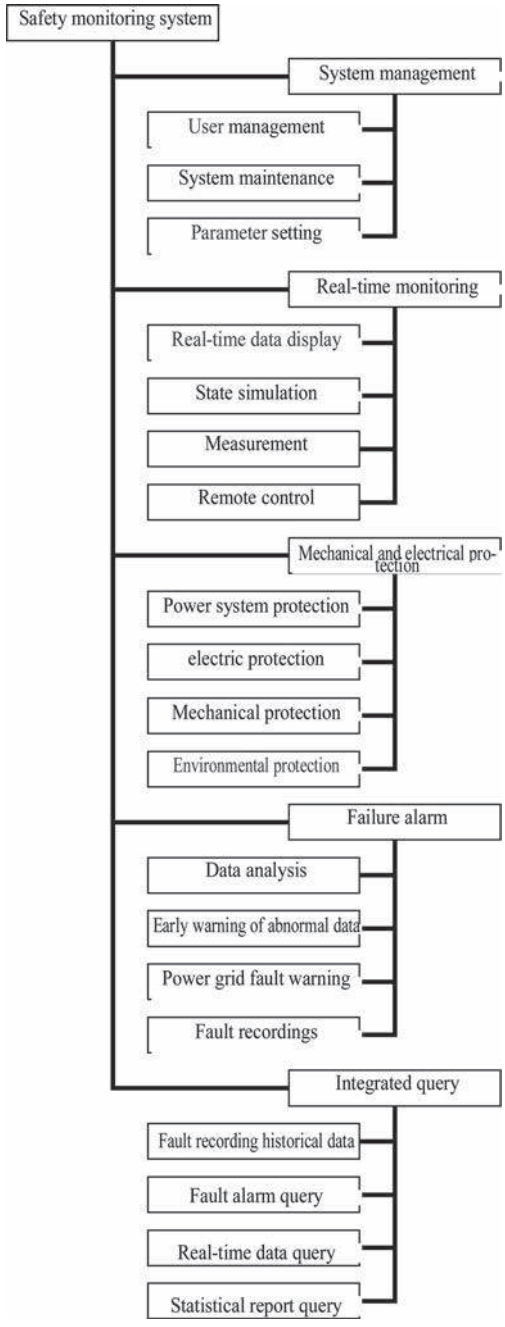

Figure 1. Mine machine safety monitoring system.

5.2 *System features*

1. Through the implementation of protection of underground electrical facilities and all kinds of fault detection, improve safety, stability operation of coal mine equipment.

2. System provides WEB data (Deng & Wei 2007) query function: users can query real-time underground monitoring equipment on the Internet, to facilitate the timely understanding of the operation situation of the underground system.
3. Some operating parameters reflect the real-time system on power system equipment, the user through the operation can observe real-time parameters of equipment.
4. system to achieve human-computer intelligent interaction in general, remote 24 hours of coal mine electromechanical equipment condition monitoring, provide a variety of information visualization of query tools, improve the management level, enhance the mine disaster and safety production capacity.

Numerical investigation of three-point bending fracture test on granite

H.J. Wang, D.A. Liu, J.R. Niu & Z.D. Cui
Key Laboratory for Geomechanics, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

F. Zhao
State Key Laboratory for Geomechanics and Deep Underground Engineering, China University of Mining and Technology, Beijing, China

ABSTRACT Three-point bending tests on specimens with different offset notches are widely used to study the propagation of mixed cracks. This paper adopts the experimental scheme that makes the loading direction perpendicular to the existing crack to investigate the I-III mixed cracks. Load-displacement curves of different offset notch positions (L = 20 mm, 30 mm) and photos of crack development can be obtained. This paper presents the numerical investigations using finite element program to obtain the stress-strain nephogram and crack trend graph. These results agree well with the experimental results. The results show that the crack nonlinear extended not only at the specimen surface but also along the thickness direction. On the other hand, the stress-strain curves and failure characteristics for specimens with different offset amounts were comparative analyzed. It can be noted that different offset amounts have great influence on the rock fracture modes.

1 INTRODUCTION

With the greater depth of the underground projects, numerous research have continually entered into underground space such as deep tunnel, coal mining, underground storage of nuclear waste and geological storage of carbon dioxide as well as shale gas exploitation (Cai M et al. 2004, Molli G et al. 2010, Jordan K. Eccles et al. 2012). Thus, the investigation of underground space is of vital importance. Due to the simple underground environment and low field stress of tens of meters under the ground, geological investigation and exploration are enough for the well run of the underground engineering. However, the underground environment will be more complicated as the human being development going into thousands of meters depth of underground space. Deep rock mass or human engineering is violently affected by the complicated mechanical environment including high stress, high temperature, high karsts water pressure and intense exploitation disturbance (He et al. 2012, K. Khan et al. 2000).

Three-point bending fracture tests on rock which can obtain the macro-micro failure mechanism have become effective mean for research (G.S. XIEDAKIS et al. 1996, G.S. XIEDAKIS et al. 1997). Some foreign researchers suggested that specimen diameter and the shape of the existing crack have great influence on the rock fracture toughness. However, the effects of loading rate, crack dimension and specimen thickness can be ignored (M.R. Ayatollahi et al. 2011, MANHANTY D K et al. 1992, Smith DJ et al. 2001, Akos Rechtorisz et al 1998). And existing crack length and offset amount can affect the specimen failure mechanism greatly by the study of mixed crack development modes in marble three-point bending test (F. Dai et al. 2011, Levent Tutluoglu et al. 2011). The double-K fracture parameters can be simply determined by three-point bending test (XU et al. 2000, XU et al. 1999). Meanwhile, the unstable crack growth trajectory can be captured by the I-III mixed loading on marble rectangular beam (Yang et al. 2011, M.R.M. Aliha et al. 2013, Tae Young Ko et al. 2013).

There are large amount of random cracks in engineering rock. And the load acted position may be apart some distance from crack location and not act along the crack propagation direction (Pan et al. 2012). Thus, this paper used the Mechanical Testing Simulation system to perform granite three-point bending test with different offset notches for the in-situ observation. The study has investigated the failure characteristics and crack development mechanism as well as different crack offset distances influence on fracture property. In addition, comparing to the experimental methods proposed by many domestic and foreign scholars, this paper has conducted the test making the existing crack

perpendicular to the loading direction. That is to say, the notch direction is set to be horizontal for the study of the I-III mixed cracks propagation. It will provide great help for the material collection of failure and stability evaluation of deep fractured surrounding rock.

2 EXPERIMENTAL PROCEDURE AND ANALYSIS

2.1 *Equipment and tested samples*

The testing equipment used in this study is Mechanical Testing Simulation system monitored by computer. The loading capacity of this testing system is 100 KN. And the main machine composes of two ball screws, a moving beam, one bottom supporting structure, four support light bars, one upper beam and four aluminum side cowlings, as shown in Fig. 1. Fixed on the experimental set, the specimen can be applied tension or compression strength through the movement of moving beam driven by ball screws.

The granite samples for these tests were cored from Laizhou, Shandong province, at the depth of 400 m. The specimen dimensions are 140 mm × 60 mm × 30 mm with the density of 2.62 g/cm3. These granite samples consisted of 38.6% quartz, 31.9% K-feldspar, 22.7% plagioclase, and 6.8% clay minerals by the analysis of X-ray diffraction. It was observed that the samples were white and intact with few native cracks.

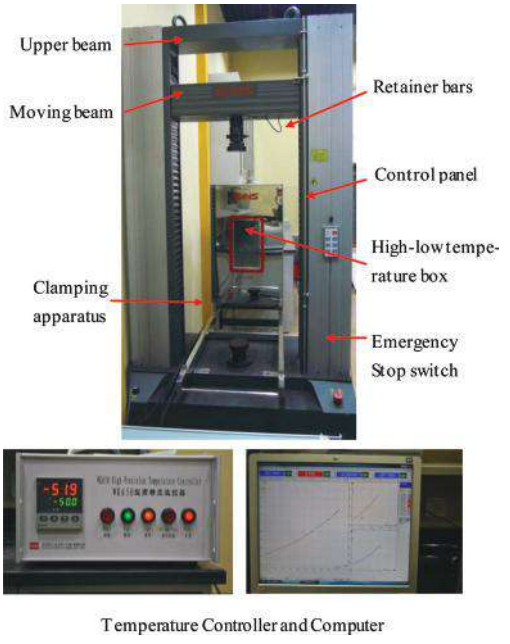

Figure 1. Photos of the experimental.

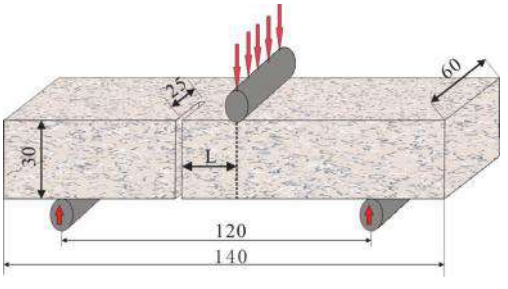
2.2 *Experimental procedure*

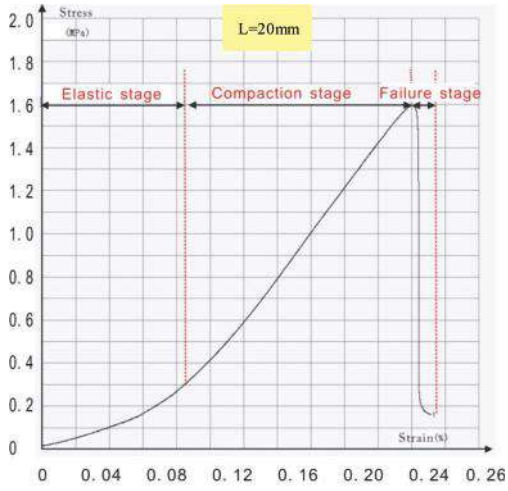
In these fracture tests, the rectangular granite specimens were used for study. To date, arranging the notch downwards in three-point bending test was popular in most research (Huang et al. 2013, Aliha et al. 2011, Ali Fakhimi et al. 2013). The new method, unlike conventional approaches, was applied in three-point bending test to observe the fracture features of granite. The distance from the media axis was determined as L and the notch depth represented was 2.5 cm. Meanwhile, the notch should be kept perpendicular to the specimen edge, shown in Fig. 2.

2.3 *Analysis of test results*

In these two tests, the notch distance from media axis L were designed as 20 mm and 30 mm respectively and the stress-strain evolution were plotted in Fig. 3.

It can be noted that the granite failure is actually the brittle fracture from the stress-strain curve. At the initial stage of the tests, both the specimens have the relatively flat development in the stress-strain curve and then the slope of the curve increase with the increasing of the strain. These can be interpreted by the appearance of the initial cracks in weak region of the specimen after being loaded. But these cracks didn't coalesce longitudinally and these micro cracks finished cracking with the increasing of the stress. Due to the system limitation for the formation of overall fracture surface, the curves enter into the second stage. The slope of the curves retain at the constant value approximately at the second stage which can be named as elastic stage. The elastic deformation belongs to the rock material properties. The strain energy is accumulated in this stage where the work





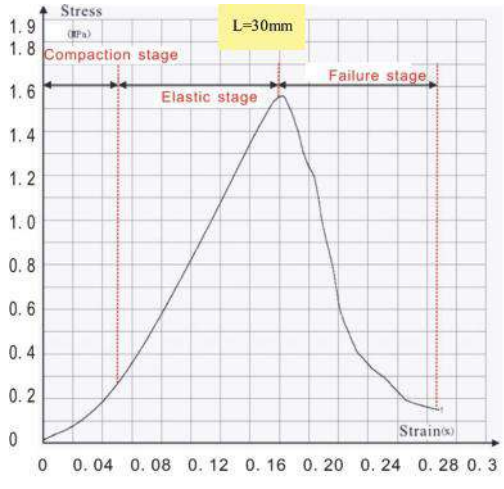


Figure 2. Specimen geometry and the three point loading configuration of the beam.

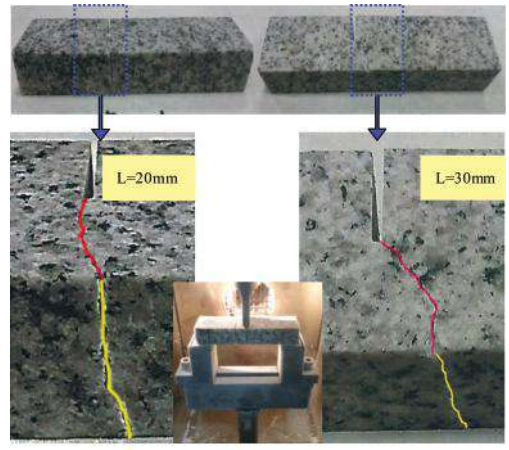

(a) Notch distance from media axis is 20mm

(b) Notch distance from media axis is 30mm

Figure 3. Stress-strain evolution for the two granite specimens.

was done from outside without making the micro cracks instability. At the third stage which is called as nonlinear failure stage, the slope of the curves decreases rapidly. The amount of the micro cracks with instable development gradually increases causing total fracture surface formation. It can be observed that the maximum failure loads for these two specimens with two notch distance values are nearly equal and there are big differences in the curves after peak value from the analysis on the stress-strain curves. The specimen with notch

(a) Notch amount L=20mm (b) Notch amount L=30mm

Figure 4. Fracture photos of the two specimens with different offset notches.

distance L of 20 mm had the brittle fracture and experienced instant destruction without any residual stress. However, the failure mode of specimen with L of 30 mm belonged to the quasi-brittle fracture. After the peak value, the stress is decreasing gradually indicating that the fracture mode is more complex.

Comparing the failure characteristics of these two specimens after the fracture, the cracks development is quite different. In Fig. 4, the red curve represents the transverse crack propagation and the yellow curve describes the longitudinal crack trend. According to the experimental field notes and images analysis, the fracture mode of the specimen with L of 20 mm is Mixed Mode I-III fracture. From the enlarged view of the crack, the form of the crack development is mainly the Mode-I fracture near the notch tip. After the Mode-I fracture (tension, opening) propagation length of 10 mm, the specimen has the Mode-III crack (anti-plane shear) propagating forward until the total fracture destruction, as shown in Fig. 4a. In the case of L = 30 mm, the crack propagation is mainly Mode-III fracture. It can be noted that two thirds of the whole crack length are shear failure from the initial cracking point at the notch tip. At about 10 mm distance from the specimen edge, the tension crack failure begin to occur which can be clearly observed from Fig. 4b.

3 NUMERICAL INVESTIGATION

This paper applied the nonlinear finite element method (Automatic dynamic incremental nonlinear

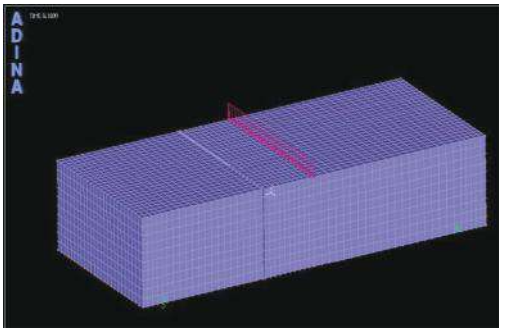

Figure 5. Mesh distribution of finite element mode.

analysis) to perform the numerical simulation [11]. Fig. 5 shows the model and the grid partition. There are a total number of 12000 units through the mesh refinement at the offset notch location. The parameters used for the numerical simulation include elastic modulus E of 53GPa, Poisson's ration γ of 0.167, density of 2.615 g/m3, the maximum tension strength of 2.6 MPa and the maximum uniaxial compressive strength of 75 MPa as well as the maximum strain of 0.22% etc. All these parameters were obtained by the conventional mechanical tests.

With the offset amount of 20 mm, the load controlled by displacement was gradually acted on the specimen. Fig. 6a shows that crack first appears at the tip of the notch and then large amount micro cracks generate inside the notch. As the load increasing, the amount of open cracks at the internal notch increase continually and the open crack at the notch tip also extends o the central region, as shown in Fig. 6b. There are many cracks appearing at the central part of the specimen where the load acted. It can be observed that a great number of closed cracks generated at the central of the specimen. Meanwhile, the red line represents the open crack and the gray line for the closed crack. According to the previous study and experimental experience, the location where large opening displacement and coalescence occur is most prone to fracture. Thus, it is consistent with the experiment result that the specimen experienced the tensile fracture at the notch finally.

As for the other case of L = 30 mm, the stress nephogram obtained by numerical results is shown in Fig. 7. Fig. 7a describes the stage of initial loading process and Fig. 7b shows the last failure process. At the initial loading stage, it can be observed that the stress concentration appear at the crack tip. The micro cracks generate at the crack tip and then develop to the lower right. With the increasing of load, the area of the stress concentration has an ascent trend, develops to the lower right

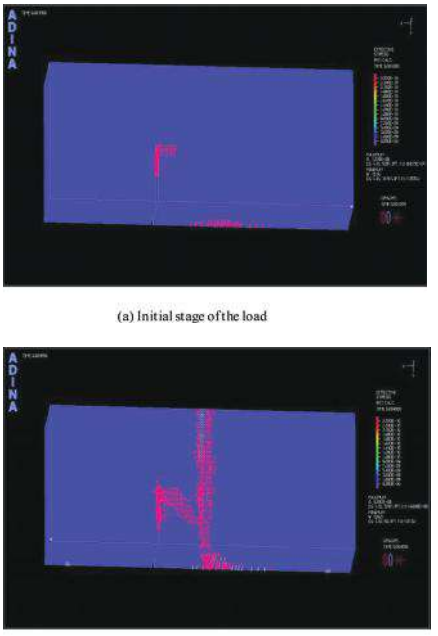

Figure 6. Numerical graphs of specimen failure process with L=20 mm.

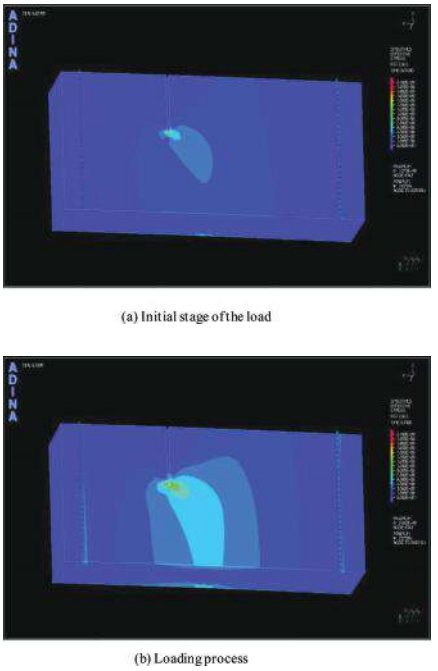

Figure 7. Numerical graphs of specimen failure process with L =3 0 mm.

gradually until propagates to the specimen edge and coalesces to failure finally. It can be noted that the failure mode of the case of L = 30 mm is mainly anti-plane shear failure from the crack formation, propagation until coalescence and equivalent stress direction. Corresponding to the tested specimen photos, these results are well agreed with the test results in Fig. 4b.

4 CONCLUSION

Basing on the new experimental method, this paper has presented the experimental and numerical investigation of the granite specimens' failure properties with different offset notches using three-point bending test. Thus, the overall conclusions of this study are hence thresholds:

1. Arranging the notch perpendicular to the loading direction, this three-point bending test can simulate the failure mode of the case that the crack propagation of the underground engineering rock mass is perpendicular to the acted loading direction.
2. The experimental procedure can be split into three stages: compaction stage for the micro cracks generation, elastic stage for strain energy accumulation of crack development and nonlinear failure stage.
3. It can be clearly observed that the failure modes for the specimens with different offset amounts are quite different by the experimental and numerical results. The specimen with L = 20 mm mainly experienced the tensile failure process whereas the I-III mixed mode (mainly anti-plane shear) for the case of L = 30 mm.

Potash exploration overview and safety considerations in Canada

J. Han
School of Management, China University of Mining and Technology (Beijing), Beijing, P.R. China

L. Piché & P. Geo
North Rim Exploration, Ltd., Saskatoon, Saskatchewan, Canada

ABSTRACT: In order to help a junior potash company undertake a successful exploration in Saskatchewan, Canada, geological information and data for the area must first be collected and analyzed. Exploration drilling is a high risk endeavor and every effort should be made to minimize risks. For illustration of exploration process and safety considerations, a drilling incident example is provided to show the importance of careful planning, proper training and clear communication. The exploration procedures and safety considerations successfully applied in Saskatchewan will benefit junior company in the development of his potash greenfield project.

1 INTRODUCTION

Potassium from potash is an important nutrient for plants and crops. As the world's population continues to increase, farmers will need to produce higher yields from less land, which supports potash demand growth of 2%-3% per year. Unfortunately, China is a country that has a shortage of potash, with 2.2% of global potash resources and 20% of the world's potash demand. Over 50% of Chinese potash consumption relies on the importation from foreign countries; meanwhile, the potash deposits in Canada are the world's single-largest source of mineable potash, comprising almost 50% of the global known potash reserves. Presently, there is great interest in exploring and developing potash deposits worldwide.

Yanzhou Coal, purchased 19 potash permits in Saskatchewan, Canada after a seven month due diligence process. The deal worth USD 260 million was inked in July 2011 and the potash property was transferred in September of 2011. Yanzhou Coal's team arrived in Saskatchewan in late 2011 to begin potash exploration and development of their properties. To date 2D seismic programs and nine drillholes have been completed. The estimated potash resources for only two of their 19 potash permits is 4.73 billion tonnes (Indicated plus Inferred resources) (Piche & Mackintosh, 2013), which is equivalent to nine times the total domestic potash resources in China.

This paper presents a summary of potash exploration and development in Saskatchewan, Canada, and provides general geological information on Saskatchewan's Prairie Evaporite Formation and safety considerations for field drilling activities.

2 GENERAL INFORMATION-YANZHOU COAL AND POTASH IN CANADA

2.1 *Yanzhou Coal*

Yanzhou Coal is an international public mining company and one of the leading producers of fertilizers and coal-based chemicals. In the mineral business, Yanzhou Coal is a leading supplier with sites in China as well as Australia and Canada. Yanzhou Coal has been listed on the Stock Exchanges of New York, Shanghai and Hong Kong respectively since 1998 and on the Australian Securities Exchange after its merger with Gloucester Coal Limited in 2012. Yanzhou Coal employs more than 100,000 people.

Yanzhou Coal aims to become a comprehensive provider of energy and fertilizer through healthy, sustainable and environmental-friendly growth, which benefits its shareholders, customers and employees. Thanks to its diversified business segments and innovative technologies, Yanzhou Coal has developed into a growth-oriented supplier of coal, coke, methanol, fertilizer and aluminium products, with the acquisition of Australian Felix Resources in 2009 and the Potash Properties in Canada.

2.2 *Potash properties in Canada*

In September 2011, Yanzhou Coal purchased 19 Potash Permits (KPs) in Saskatchewan, Canada and formed a new subsidiary—Yancoal Canada Resources Co., Ltd. ("Yancoal Canada"). Yancoal Canada owns 100% of more than 1,325,388 acres

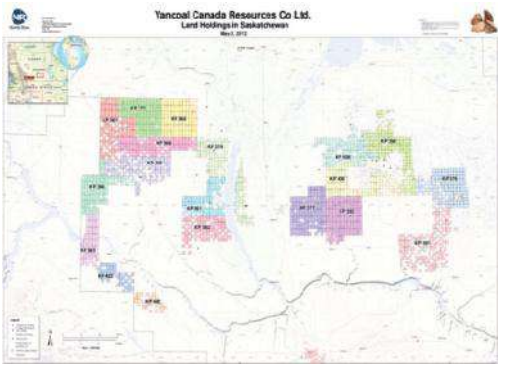

Figure 1. The location of Yancoal Canada's 19 Potash Permits.

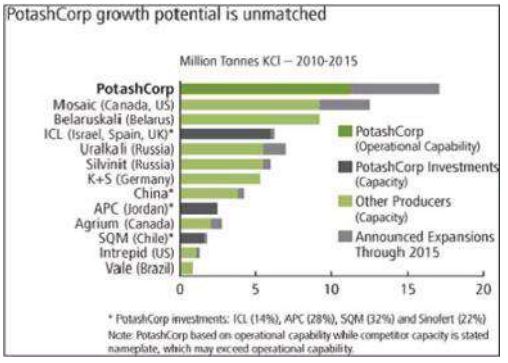

Figure 2. The World's Major Potash Producer's Capacity (From SMA Source).

(5,363.84 km2) of Potash Subsurface Exploration Permits, ranking the 3rd in position (by total acres) in Canada, after BHP Billiton and Canada Potash Corporation.

Yancoal Canada's potash property is situated in central and southern Saskatchewan, between the cities of Saskatoon and Regina (shown in Figure-1). Topography is relatively flat with gently rolling cleared farmland/pasture mixed with local poplar/aspen bluffs. The property has several positive features with regards to infrastructures. There is reasonable access to transportation facilities, natural gas pipelines, major power transmission lines, labor force and services. Water supply sources such as local underground reservoirs and natural surface water sources are currently being evaluated by Golder Associates.

Integrated with its professional mining experience, advanced mining technology and fertilizer produce and sale network, Yancoal Canada plans to become a real potash producer in Canada. Yancoal Canada is committed to local economic development while protecting environment, as they explore and develop their 19 potash permits phase by phase. Yancoal Canada began their potash exploration program and exploration activities in late 2011. The targeted plant production for Yancoal Phase-1 Project is 2.8 million tonnes per year, including production from both primary and secondary solution mining, with anticipated operation by late 2018.

3 POTASH IN SASKATCHEWAN

3.1 *Potash mining*

In general, potash deposits located at depths less than 1100 m below surface are exploited by conventional mining method. Solution mining methods are typically used for those deposits, which are deeper than 1100 m (Rubiolo, 2010).

The present time, there are three operating potash companies in Saskatchewan; Potash Corporation of Saskatchewan ("PCS"), Mosaic Potash and Agrium Inc. In 2011, the three potash producers combined produced approximately 17 million tons of KCL and had cumulative values totalling $ 6.85 billion. (MOE, 2012). Figure 2 shows the world major potash producer's capacities.

The last several decades have seen many cycles of world potash demand, the effects of which directly impact potash exploration in Saskatchewan. Saskatchewan's potash industry is currently undergoing a boom with current demand significantly increasing expansion and exploration within the province. Potash activity is presently being undertaken from existing potash producers (as Greenfield and Brownfield Projects) and junior exploration companies (as Greenfield Projects).

3.2 *Saskatchewan Potash Deposit and Geological Anomalies*

The potash deposits within Canada are the world's single-largest source of mineable potash, comprising almost 50% of the world's known potash reserve. Saskatchewan's potash resources occur within Middle Devonian Elk Point Group strata as relatively flat-lying and laterally extensive bedded deposits comprised predominantly of bedded halite (NaCl), sylvite (KCl), carnallite (KCl. $MgC_{12}.6H_2O$) and clays or insolubles. The Prairie Evaporite Formation extends from the southern extremities in North Dakota and north-eastern Montana up through southern and central Saskatchewan and into north-eastern Alberta (shown as Figure-3). The potash beds occur within the uppermost strata of a relatively thick evaporite succession known as the "Prairie Evaporite

Figure 3. Potash Deposit in Saskatchewan (From Saskatchewan Energy and Resources (SER) Website).

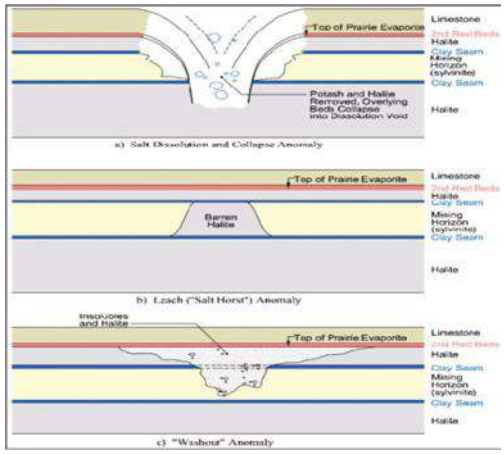

Figure 4. Anomalies Affecting Potash-bearing Bed Geology.

Formation", which essentially is comprised of a broadly distributed salt deposit with anhydrite interbeds. Three potash units may be present including (from the base to uppermost) the Esterhazy, Belle Plaine, and Patience Lake Members (Holter, 1969).

The potash-bearing beds may be affected by three general types of anomalies, a) Salt dissolution and collapse, b) Leach anomalies, and c) Washout anomalies. In general, a disturbance that affects the normal character of the sylvinite-bearing beds is considered an "anomaly" and, thus, represents an area which is not suitable for mining. The impact of these types of anomalies on mining operations is that the grade of the potash ore being sent to the mill drops as mining cuts through anomalous ground, or that a portion of the potash ore reserve is left in the ground as mining operations abandon the anomalous ground as a safety pillar surrounding it. Figure 4 illustrates the types of disturbances that created anomalous altered zones within the main sylvinite-bearing beds as is typical for Saskatchewan potash mining properties (Halabura & Hardy, 2007).

4 POTASH EXPLORATION

The two main methods of data acquisition used for determining the geology and delineation of a potash Mineral Resource are seismic programs (either 2D or 3D) and drilling with core retrieval.

Seismic: Reflection seismic methods can be used to create images of the geologic changes and some of the above discussed anomalies. 2D and 3D seismic surveys are highly effective subsurface analytical tools for potash exploration used in the identification and estimation of the degree of salt loss, salt dissolution-induced collapse structures, and the identification of other geological elements. These seismic programs can help complete a picture of the subsurface that should enhance the ability of the exploration team to successfully select well locations.

Drilling: Holes or wells are drilled in areas where the 2D and 3D seismic survey indicated as favorable for potash mineralization or for investigation of geological structures. Drilling further defines the extent, grade and type of potash mineralization present on the property and provides further calibration for interpretation of seismic data. Holes are drilled vertically targeting the Prairie Evaporite formation, which are conventionally cored using invert or brine drilling fluids so as not to dissolve the salt and potash sequences. Samples are collected from the potash sequence for observation and assay analysis, and each hole is logged using industry-standard down-hole geophysical logging techniques.

5 SAFETY CONSIDERATION

Mineral exploration, by nature is a high risk activity. The safety consideration, risk assessment and risk mitigation plans are paramount for successful exploration portfolio management. Some of the key factors and consideration for safe and smooth drilling activity are the following:

- Select a reputable exploration management company with relevant experience in the potash sector;
- Collect and analyze all historical and existing data and information on the targeted area;
- Complete seismic programs prior to drilling to help locate well;
- Combine the experience and talent of the seismic team and the exploration team during selection of the well location to minimize risks of encountering anomalies;

- Select suppliers and field operators with strong safety records and training;
- Have in place a well-arranged schedule and emergency plan for potential incidents and risks;
- Plan at all times for prompt and effective communication between operator, field team and local government.

In the following, one the Saskatchewan potash exploration wells completed by a Junior company is provided as an example of how risk was mitigated and managed using the above considerations. During the drilling of an exploration well, while coring the Prairie Evaporite Formation, fluids (brine) were encountered with unusually high pressures. The blow-out preventers (BOP's) were immediately shut to ensure a blow-out would not occur. Following the initial pressure kick the drilling fluid (or mud) was continually "weighted up" (addition of barite to the drilling fluid in an effort to push pressurized fluids back into the formation) and circulated in the hole in an attempt to secure the well until the well was cemented in and abandoned.

Prior to the drilling of the well all geological data, including the seismic was thoroughly reviewed and analyzed. From the data at hand there was no reason to expect an influx of fluid during the second core run in the Prairie Evaporite Formation. Not only is it unusual to encounter fluids in the middle of the salt bed, the pressures encountered in this well are abnormally high for the potash exploration industry. The zero casing and drill pipe pressure was achieved when the fluid column was at 2000 kg/m3. This equates to a bottom-hole pressure of approximately 30 MPa which is hydrostatically over-pressured by about 15 MPa.

Although this incident was an unfortunate situation to encounter while drilling, all parties involved were diligent and responsible when determining the correct solution to implement. Due to safeguards put in place prior to the start of drilling and the incident of pressurized brine, this well did not experience a blow-out and there were no injuries to field personnel or to the environment. The following success factors attributed to preventing a blow-out.

1. Blow-Out Preventers (BOPs):
   - Proper sized BOPs were used in the drilling operations to counteract the pressures experienced in the wellbore.
   - The BOPs were inspected and tested regularly as per government regulations.
2. Casing Installation:
   - Casing was installed from surface to core point which contained the fluid/pressure in the wellbore (including surface and intermediate casing). This intermediate casing is not installed in all potash wells in Saskatchewan.
   - Casing was cemented from surface to core point which prevented casing from bursting under pressure. Some Saskatchewan potash wells only "tack" the intermediate casing in. There is speculation that the high pressures in this well may have dislodged the intermediate casing if it had only been tacked in place.
3. Operations:
   - Casing and BOPs were pressure tested prior to drilling out casing shoe.
   - Drillers and well supervisors had proper training and certificates in "First Line Supervisor's Blowout Prevention" and "Second Line Supervisor's Well Control", respectively. They not only had the training, but were prompt and accurate with implementation protocols outlined in these training and certificate programs.

6 CONCLUSION AND RECOMMENDATIONS

Presently, the potash sector in Saskatchewan, Canada is booming. Yancoal Canada is progressing with the development of their Saskatchewan potash properties using the methodology that an effective and well-organized exploration program is the key factor for junior potash exploration companies and their Greenfield Project. For illustration of exploration process and safety considerations, a drill incident example is provided to show the importance of careful planning, proper training and open, clear communication.

In undertaking a potash exploration and development project, the first priority task is to estimate the amount and quality of potash contained within the targeted potash permit area. This paper demonstrates the importance of collecting and analyzing existing geological data prior to completing drilling programs in order to minimize risks from geology anomalies. Outside of geology knowledge, safety considerations, risk assessment and risk mitigation plans are paramount for successful exploration portfolio management. Some of the key factors and consideration for safe and smooth drilling activity are the following:

- Select a reputable exploration management company with relevant experience in the potash sector;
- Collect and analyze all historical and existing data and information on the targeted area;
- Complete seismic programs prior to drilling to help locate well;

- Combine the experience and talent of the seismic team and the exploration team during selection of the well location to minimize risks of encountering geological anomalies;
- Select suppliers and field operators with strong safety records and training;
- Have in place a well-arranged schedule and emergency plan for potential incidents and risks;
- Plan at all times for prompt and effective communication between operator, field team and local government.

ACKNOWLEDGEMENTS

Experimental study on high temperature shear strength parameter of salt rock

Kun Fang, Yun-Peng Li, Wei-Wei Bi & Jin-Peng Wu
College of Mechanical and Transportation Engineering, China University of Petroleum, Beijing, China

ABSTRACT: In order to research the thermal effect's law of shear strength parameters of rock salt under high temperature condition, the triaxial compression tests of two place's salt rock under different high temperatures and different confining pressure are carried out. Salt rock thermal damage variable is defined, exported shear strength parameters under the condition of the different high temperature and its thermal damage relationship. The research indicated that with the increase of temperature, salt rock thermal damage also increases, the shear strength parameters of rock salt deteriorated significantly, shear strength and triaxial compressive strength is gradually attenuation trend. Two area's salt rock shear strength parameter and intensity values different, but have the same attenuation trend. this analysis method can be used for salt cavern stability evaluation analysis reference.

1 INTRODUCTION

Salt rock is a soft rock with low intensity, large deformation. Because of the very low permeability, good creep, injury healing, and other characteristics, salt rock is widely used as energy storage medium. Mechanical properties of rock salt in the Underground Storage will be affected by temperature, the impact of temperature on rock salt is mainly reflected in the mechanical properties (strength, deformation) and thermal characteristics (linear expansion, thermal conductivity, specific heat, temperature, conductivity) etc. Therefore, scholars have undertaken extensive research on the thermodynamic properties of rock salt. As in literature 1, through a series of tests for heated salt rock at different temperatures, Obtains the relationship between compressive strength and axial strain along with temperature change under the high temperature function. As in literature 2, testing studies is made on the mechanical properties of rock salt after undergoing different high temperatures, The mechanical properties include stress—strain curve, peak stress, peak strain, modulus of elasticity. There are other scholars on these issues were also made by the appropriate research and obtain valuable results, as in literature 3–7. Nevertheless, due to the particularity of rock salt and its engineering use, the thermal effect of the salt rock is still much widespread concern. According to the salt rock triaxial compression under different temperature conditions in this article, it analyses the change rules of shear strength parameters of rock salt in different confining pressure, different temperature conditions. Introduction of heat damage variable, establish the high temperature shear strength parameters of rock salt, rock salt triaxial compressive strength and thermal damage factor with temperature changes in relationship, and the corresponding thermal effects of the law is discussed.

2 RELATIONSHIP BETWEEN HIGH TEMPERATURE SHEAR STRENGTH PARAMETERS AND TEMPERATURE

As the temperatures rising, salt rock's internal moisture evaporation and drying increases, molecular thermal motion increased, weakening its grain and the cohesive force between the particles. In addition, as the temperature increase, the internal crack source of rock salt growth and micro-cracks probability increases. It caused the salt rock's skeleton mineral particles and the structure of the fine view changed, which is damage. With the continued accumulation of this damage, resulting in the continuous degradation of shear capacity of the salt rock and reduce. This strength deterioration could embody in the damage characteristics of the shear strength parameters of rock salt. High temperature conditions, the shear strength of rock salt are not only related to temperature changes, and also have a certain relationship with the micro-damage of the rock salt's structure.

As in literature [8], Mohr-coulomb strength conditions considering temperature effects can be expressed as follow.

$$\sigma_1(T,\sigma_3) = m(T)\sigma_3 + b(T) \tag{1}$$

m(T), b(T) is triaxial compressive strength parameters.

$$\left.\begin{aligned} m(T) &= \frac{1+\sin\varphi(T)}{1-\sin\varphi(T)} \\ b(T) &= \frac{2C(T)\cos\varphi(T)}{1-\sin\varphi(T)} \end{aligned}\right\} \tag{2}$$

According to the Mohr—Coulomb strength conditions and salt rock shear strength thermal damage, thermal damage factor as (3).

$$\left.\begin{aligned} \varphi(T) &= \arcsin\left[\frac{m(T)-1}{m(T)+1}\right] \\ c(T) &= \frac{b(T)[1-\sin\varphi(T)]}{2\cos\varphi(T)} \end{aligned}\right\} \tag{3}$$

C(T), φ(T) is salt rock cohesion and the angle of internal friction when temperature is T.

Define thermal damage factor as follow.

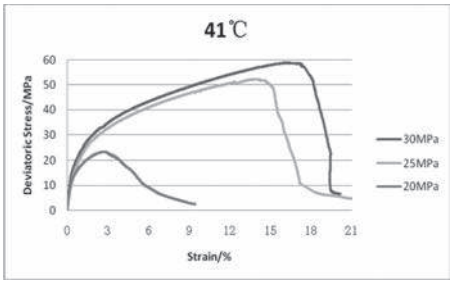
$$\left.\begin{aligned} D_C(T) &= 1-\frac{C(T)}{C(T_0)} \\ D_\varphi(T) &= 1-\frac{\varphi(T)}{\varphi(T_0)} \end{aligned}\right\} \tag{4}$$

$C(T_0)$ is the cohesive force of room temperature; $\varphi(T_0)$ is the internal friction angle of room temperature; $D_C(T)$, $D_\varphi(T)$ respectively be the damage factor when temperature is T. (4) is organized as follow.

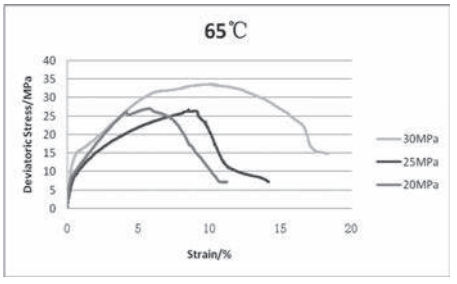
$$\left.\begin{aligned} C(T) &= C(T_0)(1-D_C(T)) \\ \varphi(T) &= \varphi(T_0)(1-D_\varphi(T)) \end{aligned}\right\} \tag{5}$$

The above equation is the shear strength parameters of rock salt with temperature relationship which represented by the thermal damage factor. Thus, once the salt rock thermal damage factor variation with temperature is obtained, it can get different salt rock under high temperature shear strength parameter values as long as known salt rock strength parameters.

Take (5) and (2) into (1) to obtain the relationship between three axial compressive strength and thermal damage factor for salt rock, as (6).

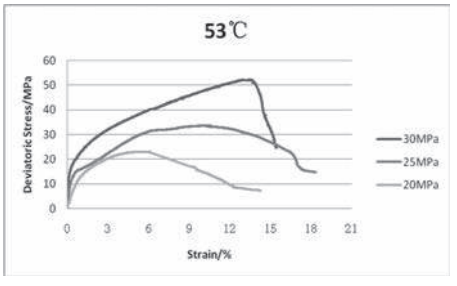


$$\begin{aligned} \sigma_1(T,\sigma_3) = {} & \frac{1+\sin\left(\varphi(T_0)(1-D_\varphi(T))\right)}{1-\sin\left(\varphi(T_0)(1-D_\varphi(T))\right)}\sigma_3 \\ & + \frac{2\left(C(T_0)(1-D_C(T))\right)\cos\left(\varphi(T_0)(1-D_\varphi(T))\right)}{1-\sin\left(\varphi(T_0)(1-D_\varphi(T))\right)} \end{aligned} \tag{6}$$

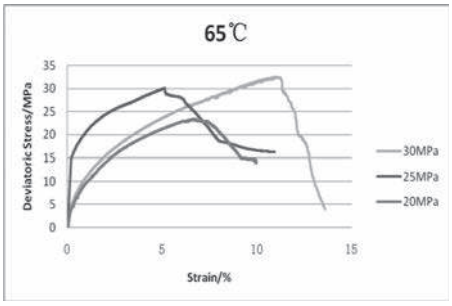


3 HIGH-TEMPERATURE STRENGTH PARAMETERS OF ROCK SALT TEST

3.1 *High temperature triaxial tests of rock salt*



Sample using rock salt core which at different depths of two reservoirs, salt rock is white or grey, it is diameter 50 mm, height 100 mm standard cylinder. The test is divided into at room temperature, 41°C, 53°C, 65°C, each temperature is divided 20 MPa, 25 MPa, 30 MPa. Some of the test curve as shown in figure 1.



Using the pressure of the triaxis compression curves under same temperature, obtain triaxial compressive strength parameters m and b values of rock salt in each temperature. Through (3), get the shear strength parameters of rock salt is different under high temperature condition, namely the cohesion and internal friction angle, are listed in table 1. From table 1, it can be seen at high temperatures, parameters m and b decrease with the increasing temperature, the cohesion and friction angle have the same regularity. The shear strength parameters under two areas have significant differences.

(a) Triaxial compression curves at two temperatures in reservoir A

(b) Triaxial compression curves at two temperatures in reservoir B

Figure 1. Rock salt high temperature triaxial compression test curve.

Table 1. Cohesion and internal friction angle in different temperature.

Storage cavern	Temp °C	m	b	C/Mpa	φ/(°)
1	29	3.024	9.024	2.82	30.2
	41	2.673	8.731	2.67	27.1
	53	1.904	6.319	2.29	18.13
	65	1.907	6.058	2.19	18.18
2	29	3.679	4.931	1.29	34.93
	53	2.657	2.983	0.92	26.94
	65	2.053	2.063	0.72	20.17

3.2 *Salt rock strength thermal damage effect*

The damage factor of the salt rock which using table 1 and the (4) at different temperatures are listed in table 2. The change law of the thermal damage factor with temperature as shown in figure 2. From table 2 and figure 2 can be seen, as the increasing temperature, the damage value also increased, two area rock salt thermal damage factor was increased with increasing temperature. The two rock salt thermal damage factor in one reservoir consistent trends, reservoir 1, after the temperature reaches 53°C it has slowdown trend.

The change law's approximation fitting equation of two reservoir thermal damage dependence of temperature as follow.

$$\left.\begin{aligned} D_{c1}(T) &= -0.848e^{-0.01741T} + 0.52 \\ D_{\varphi 1}(T) &= -1.659e^{-0.03924T} + 0.51 \end{aligned}\right\} \tag{7}$$

$$\left.\begin{aligned} D_{C2}(T) &= -1.819e^{-0.04424T} + 0.50 \\ D_{\varphi 2}(T) &= -2.266e^{-0.03977T} + 0.71 \end{aligned}\right\} \tag{8}$$

The two reservoir's relationship between shear strength parameters and temperature as follow.

$$\left.\begin{aligned} C_1(T) &= C_1(T_0)(1 + 0.848e^{-0.01741T} - 0.52) \\ \varphi_1(T) &= \varphi_1(T_0)(1 + 1.659e^{-0.03924T} - 0.51) \end{aligned}\right\} \tag{9}$$

Table 2. Thermal damage to the value of rock salt at different temperatures.

Storage cavern	Temp °C	29	41	53	65
1	$D_{C1}(T)$	0	0.053191	0.187943	0.222163
	$D_{\varphi 1}(T)$	0	0.109814	0.355735	0.382339
2	$D_{C2}(T)$	0	0.144064	0.288137	0.439907
	$D_{\varphi 2}(T)$	0	0.269954	0.439907	0.581659

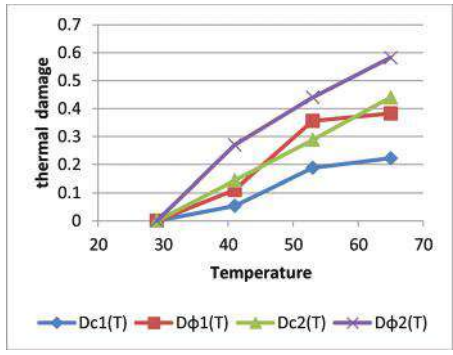


Figure 2. Rock salt thermal damage factor and temperature curves.

$$\left.\begin{aligned} C_2(T) &= C_2(T_0)(1 + 1.819e^{-0.04424T} - 0.50) \\ \varphi_2(T) &= \varphi_2(T_0)(1 + 2.266e^{-0.03977T} - 0.71) \end{aligned}\right\} \tag{10}$$

Take (7) and (8) into (6) type, obtained two change laws of rock salt triaxial compressive strength as the change of temperature.

Take 53°C , 65°C as the example, salt rock shear intensity parameter as shown in table 3 which using (9) and (10). Combine Table 3 and (1) can obtain the salt rock triaxial compressive strength under different temperature (20 MPa confining pressure as example) as Table 4. From Table 3 and Table 4, it can be seen that the salt rock shear strength increased with the temperature decrease, mean the salt rock strength degradation with the temperature increased, and salt rock shear strength parameters of two reservoirs have the same regularity. Through this Table or analysis method can be conveniently obtained the thermal damage or attenuation coefficient of salt rock shear strength. By (9), (10), (11) and (12) clearly visible, if the salt rock thermal damage factor with temperature variation was obtained by the test, it can convenient obtain the salt rock shear strength parameters thermal damage equation only by the normal temperature test, which can be used as a salt cavern gas storage security and stability evaluation of mining operation in the note reference.

$$\sigma_1(T,\sigma_3)\big|_{K1} = \frac{1+\sin\left(\varphi(T_0)(1+1.659e^{-0.03924T}-0.51)\right)}{1-\sin\left(\varphi(T_0)(1+1.659e^{-0.03924T}-0.51)\right)}\sigma_3 + \frac{2\left(C(T_0)(1+0.848e^{-0.01741T}-0.52)\right)\cos\left(\varphi(T_0)(1+1.659e^{-0.03924T}-0.51)\right)}{1-\sin\left(\varphi(T_0)(1+1.659e^{-0.03924T}-0.51)\right)} \quad (11)$$

$$\sigma_1(T,\sigma_3)\big|_{K2} = \frac{1+\sin\left(\varphi(T_0)(1+2.266e^{-0.03977T}-0.71)\right)}{1-\sin\left(\varphi(T_0)(1+2.266e^{-0.03977T}-0.71)\right)}\sigma_3 + \frac{2\left(C(T_0)(1+1.819e^{-0.04424T}-0.50)\right)\cos\left(\varphi(T_0)(1+2.266e^{-0.03977T}-0.71)\right)}{1-\sin\left(\varphi(T_0)(1+2.266e^{-0.03977T}-0.71)\right)} \quad (12)$$

4 CONCLUSION

A: Use the salt rock shear strength parameters for the thermal damage variable, it defines the thermal damage factor of rock salt shear strength, and derived the variation of salt rock strength and thermal damage factor under the condition of high temperature, which can describe the influence of high temperature environment for effective change of salt rock strength regularity.

B: With increasing temperature, salt rock strength and shear strength parameters deteriorated significantly damage, manifested as the shear strength parameters of rock salt decreases, compressive and shear strength showed a significant attenuation of the trend. Rock salt of two reservoirs shear strength parameter values, although some differences, but it has the same regularity.

Table 3. Different regions of the salt rock shear strength parameter compared with the temperature variation.

Storage cavern	Temp °C	Test data		Damage effects	
		C/MPa	φ/(°)	C/MPa	φ/(°)
1	53	2.29	18.13	2.33	21.06
	65	2.19	18.18	2.15	18.71
2	53	0.92	26.94	0.87	19.75
	65	0.72	20.17	0.99	16.10

Table 4. Triaxial compressive strength of rock salt at different temperatures compared (confining pressure is 20MPa).

Storage cavern	Temp °C	Test data	Damage effects
1	53	44.37480	49.21047
	65	44.17439	44.87736
2	53	56.10366	42.86848
	65	43.09773	37.95315

C: With rock salt temperature test, using thermal damage factor analysis method, can easily get high triaxial compressive strength of rock salt with temperature-dependent thermal effect equation, and the shear strength parameters of rock salt thermal damage formula, which are for salt cavern gas storage injection and production operations evaluation and analysis of the security and stability of reference.

Fast verification method of mining mechanical anemometers based on wind speed equivalent weight

Wen-Yao Ni
Key Laboratory of Hebei Province for Mine Disaster Prevention, Safety Engineering School, North China Institute of Science and Technology, Yanjiao, Beijing-East, China

Wen-Mei Gai
Civil and Environmental Engineering School, University of Science and Technology Beijing, Beijing, China

ABSTRACT: The problems in the current domestic use of the pitot tube combining micro-manometer to verify the mining mechanical anemometers were analyzed. Based on the structure principle of hydrodynamics, under the premise of the test with no violation of the orders anemometer verification, a new method based on wind speed equivalent weight to verify the anemometer was introduced. And the field test in the scene of the Key Laboratory of Hebei Province for Mine Disaster Prevention demonstrates that this method is a simple, fast, and accurate method to verify the mining mechanical anemometers within the expiration date of the wind tunnel.

Keywords: Machinery anemometer, pitot tube & micro-manometer method, air velocity equivalent weight metho, verification

1 INTRODUCTION

"Coal Mine Safety Regulations" provides in No.106 issue for that: "Mine must have a sufficient number of ventilation safety testing instruments, meters must be authorized by the National Safety Instrumented measurement units qualified to carry out inspection."

In the early 1960s, came the domestic application of anemometer verification with low-speed wind tunnel. The current mining anemometer verification adopts "Orders of Mining Anemometer Verification" (JJG01–96) promulgated by the original Coal Industry of China in 1996, which provided that the period of anemometer verification is six months. In this verifying method, the dynamic pressure of air current is measured by the pitot tube & micro-manometer, which is converted into the actual air velocity, and then drawn into a calibration curve with the anemometer readings, used together with the anemometer.

At present, for the resolution ratio in reading the compensated micro-manometer currently used in china is 0.1 pa, errors comes easily in reading the micro-manometer when measured at low air speed (to lower dynamic pressure). In the meantime, the micro-manometer adjustment process before reading is more time-consuming, particularly for the fine-tuning reading. Therefore it is necessary to improve the method of anemometer verification. Under the premise of according with the orders of anemometer verification, a fast method of anemometer verification was introduced in the text.

2 FAST VERIFYING METHOD OF ANEMOMETER—AIR VELOCITY EQUIVALENT WEIGHT METHOD

According to the Proportion Law of ventilator in hydrodynamics, the air flow in the wind tunnel and the ventilator speed is in direct proportion, so is the air speed of any point and the wind speed, for the cross-section of any point in the wind tunnel is constant. And the Verification of speed can be fast and accurate. Whereas the above analysis, the corresponding relation equation of them can be built up with determination of the air speeds to different ventilator speeds, improving the pitot tube & micro-manometer method, which is process-complicated and time-consuming with greater error in lower air velocity, into a method of calculating air velocity with determination of the ventilator speed, called the air velocity Equivalent weight method.

2.1 *The determination arrangement*

Fig. 1 is the sketch map of technical determination arrangement for correcting anemometer. After

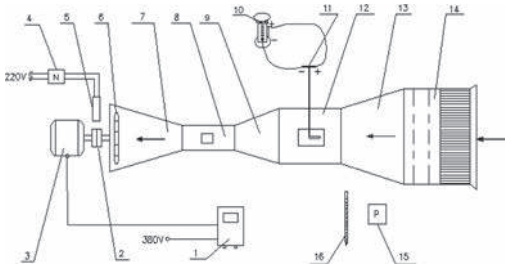

Figure 1. Sketch Map Of Technical Determination Arrangement.
1-Electronic control box, 2-Axle connecting machine, 3-DC motor, 4-Digital Speed Display, 5-Photoelectric speed sensor, 6-Air impeller 7-the proliferation segment, 8-High-speed segment, 9- the second contraction segment, 10-the compensated tasimeter, 11-Pitot tube, 12-Medium-speed segment, 13-the first contraction segment, 14-Rrectification segment, 15-Barometer, 16-Thermometer.

Axial-flow exhaust fan is activated by the speed control DC motor, then the air current enters into the XRS-type testing wind tunnel when it is rectified, with airflow speed changed through a second contraction and once diffusion in the wind tunnel. When to its maximum permissible speed of 2800 rpm, wind speeds to three experimental segments in the wind tunnel are 2.61 m/s, 15.44 m/s and 48.67 m/s. Select corresponding experiment segment to correct according to the measuring range of the mining anemometer when verification.

The silicon controlled rectification automatic speed-control system was adopted in the adjustment of the ventilator speed. There are two: First, the "stepless speed regulation" is the adjustment in the largest range of biggest ventilator speed fan in any way; second, the "fixed speed" is, for each test segment, setting up multiple sets of fine-tuning potentiometer, and setting the value of many groups under the required speed.

2.2 *Parameter measurement*

2.2.1 *Parameter measurement of ventilator speed*

To measure the ventilator speed by the digital speed display combined with the photoelectric speed sensor,

$$n = \frac{60z}{H \cdot t} \tag{1}$$

where: n indicates actual fan speed, rpm, z is signal number showed by Speed Display, H indicates signal number given by the ventilator in a cycle, t is measurement time, s.

2.2.2 *Actual air velocity measurement in the experimental segment*

To measure the air velocity by pitot tube combined with the compensated micro-manometer.

$$v = \left(\frac{2\xi h_v}{\rho} \right)^{0.5} \tag{2}$$

where: v is the actual air speed, m/s, ξ is current coefficient of pitot tube, authenticated that ξ = 1.004, ρ indicates the density of humid air, kg/m^3, h_v indicates airflow pressure, pa.

$$\rho = \frac{C \cdot P}{T} \tag{3}$$

where: P is the actual atmospheric pressure of measurement location, hpa, C is coefficient without calculating partial pressure of saturated steam, ks^2/m^2, P is actual atmospheric pressure in the location, hpa, considered common conditions and the actual situation in underground coal mines of anemometer verification, t generally between 10~30 °C, when C = 0.346, T is the thermodynamic temperature of the air in the location, K.

$$T = 273.15 + t \tag{4}$$

where: t – temperature of the dry air in the location, °C.

$$h_v = \rho_t \cdot g \cdot h \tag{5}$$

Where: ρ_t is the density of pure water at temperature t, kg/m^3, in the experimental test conditions, its value varies at 0.99673~0.99715, approximate values for the 1.0. g is the gravity acceleration of the location, Xuzhou region as 9.81 m/s^2, h is height of the water column of the compensated tasimeter, mm.

Return Eqn. (3), (4), and (5) also parameter values of ξ, C, and ρ_t etc. into Eqn. (2) and get the computational formula of actual air speed as:

$$v = \left[56.932h \frac{(273.15+t)}{P} \right]^{0.5} \tag{6}$$

2.2.3 *Test result*

The authors have tested the mining mechanical anemometers in the scene of the Key Laboratory of Hebei Province for Mine Disaster Prevention based on the air velocity Equivalent weight method. The anemometers were verified in the medium-speed segment of the wind tunnel with the above-mentioned arrangements and

Table 1. Datum of speed and air velocity determined of the XRS-type wind tunnel.

Serial Number	P/hpa	t/°C	ρ/kg·m^{-3}	h/mm	n/rpm	v/m·s^{-1}
1	1003	24.8	1.1648	0.034	168.1	0.76
2	1003	24.8	1.1648	0.061	230.1	1.01
3	1003	24.6	1.1655	0.245	408.1	2.03
4	1003	24.7	1.1651	0.551	615.0	3.05
5	1003	24.8	1.1648	0.980	819.9	4.06
6	1003	24.9	1.1644	1.532	1017.3	5.08
7	1003	25.1	1.1636	2.205	1218.9	6.10
8	1003	25.3	1.1628	3.921	1615.3	8.14
9	1003	25.7	1.1612	6.127	2027.7	10.18
10	1003	25.9	1.1605	8.823	2428.6	12.22
11	1003	26.2	1.1593	12.01	2835.5	14.26

computational formula. The measured results can be seen in Table 1.

The relational equation between the n and v was obtained by data regression of them showed in Table 1 as:

$$v = 0.0051n - 0.0847 \quad (7)$$

Its dispersion is $R^2 = 1$, which shows that the proportional liner relationship between the n and v is more obvious. Similarly, the corresponding segment in the high-speed wind tunnel, the above-mentioned methods can also be used to draw the equivalent relationship between n and v, and not to recount it here.

2.3 *Example analysis of anemometer correction*

For example of medium-speed anemometer verification, dismantle the pitot tube and the compensated micro-manometer showed in Fig. 1, have the anemometer to be verified installed in the axis of the medium-speed segment in the wind tunnel with other arrangements remained.

Verify air velocity by 6 points (maximum speed of not more than anemometer range) With "fixed-point" approach from low-speed to high-speed from low speed to high speed, read the n and the x to the ventilator speed and the anemometer at each measuring point. For the atmosphere condition when verifying the anemometer was near to that of the actual velocity determination in the air velocity Equivalent weight method (the relevant parameters seen in the Table 2), so the air density correction is omissible. So that the actual air velocity v to each measuring point can be worked out with the ventilator speed v substituted into Eqn. (7) directly. Finally, draw the corrective curve of the anemometer with v and x (see Fig. 2), obtaining the fitted equation (also called corrective formula

Table 2. Verifyed data of medium-speed anemometer Anemometer number:2132.

Serial Number	P(hpa)	T(°C)	N(rpm)	V(m·s^{-1})	X(case·min^{-1})
1	1004	25.2	153.7	0.69917	26.5
2	1004	25.2	465.2	2.28782	138.6
3	1004	25.1	863.7	4.32017	281.7
4	1004	25.1	1261.9	6.35099	413.8
5	1004	25.1	1657.4	8.36804	555.6
6	1004	24.9	2011.9	10.17599	678.0

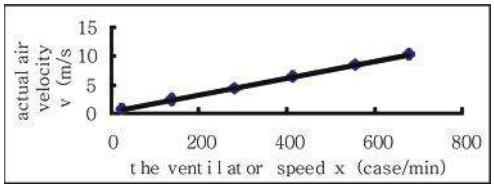

Figure 2. Corrective curve of the anemometer.

of anemometer) of the relationship between them from the curve as well, as:

$$v = 0.0146x + 0.2781 \quad (8)$$

The regression dispersion of the equation is $R^2 = 0.9999$, much approaching to 1, so the curve fits well.

Up to this point, the anemometer on the finish of the fast and accurate verification could be attached to anemometer calibration box with the above-mentioned corrective curve anemometer and the formula, to be used together with the anemometer in the normal usage period until the next correction.

3 CONCLUSIONS

1. Based on the Proportion Law of hydro-mobility of hydrodynamics, with the standard wind tunnel, measured with the standard calibration of the Department, the relationship equation between the actual ventilator speed and the actual air velocity inside the wind tunnel was set up. It can be corrected traditionally with the anemometer readings and the actually tested air velocities for comparison, which has been improved to be the correction method of anemometer readings compared with the ventilator speeds, which is the equivalent wind speed law.
2. The method of equivalent air velocity to verify the anemometer, only needs to standardize the relationship between the ventilator speed and the actual air velocity once, simply in the pitot

tube and micro-manometer method of ministerial orders, Then the anemometer can be verified fast and accurately by determination of the ventilator speed. It has overcome the defects of time-consuming and easy with reading errors etc. brought about by the pitot tube and micromanometer installment during traditional correction of anemometer each time.

3. Whether the equivalent velocity method or the traditional one, only can be used in the valid period of the standard wind tunnel. To the standard wind tunnel itself, it must also be periodically corrected in accordance with the relevant standards. If there is damage in the use of its period, in the absence of rehabilitation and correction by the former, it shouldn't be used for the job of the anemometer calibration.
4. Under normal circumstances, for the year-round change of air density in the mine area is very small, the anemometer can be corrected directly in the method introduced in the text. However, when the anemometer calibration and the test of equivalent velocity, or the usage and the correction of anemometer, are to the large difference in atmospheric conditions (such as the anemometer corrected in the plains used in high altitude), air density must be corrected accordingly in the use of the air velocity Equivalent weight method to verify the anemometer.

Development of a new kind of safety helmet of underground miner for emergent hedge

Xiao-Ming Liu, Yu-Kun Gao, Zhi-An Huang, Ying-Hua Zhang, Yan-Feng Zhang & Qian Zhao
State Key Laboratory of High-Efficient Mining and Safety of Metal Mines, University of Science and Technology Beijing, Ministry of Education, Beijing, China

ABSTRACT: According to fact that traditional safety helmet can only protect head of wearer, on the basis of traditional helmet, by using computer-assisted method, a new kind of safety helmet of underground miner for emergent hedge was developed. In case of danger, through releasing adiabatic protective material beneath brim of the helmet, a confined space can be formed at head position of wearer as eye vision of wearer can be assured. Experimental results show that as temperature rises over time, order of temperature from highest to lowest is temperature at the face position, temperature at the front of head, temperature at the back of head and temperature over head. Through comprehensive analysis of experimental results, conclusions can be drawn as follows: the optimal oxygen supplying method is supplying oxygen vertically at the front of head and making air flow out from the bottom, and the optimal oxygen supplying speed is 0.1 m/s, moreover, inlet air temperature should stay at about 300 k. The research result can supply new program of emergent hedge for underground miner.

1 INTRODUCTION

Many kinds of accidents would happen during process of coal production, such as fire, gas explosion, sudden gush out of harmful gases and so forth. A safety helmet is one of the protective equipments which underground miners have to wear.

Traditional mine safety helmets can only defend impacts coming from space above head. When mine disaster such as mine fire or gas explosion happens, miners' faces often completely expose to harm such as sudden gush out of flue gas, toxic or harmful gases and so on, but there are often no proper device or equipment to offer protection. Although some innovations and improvements of traditional mine safety helmets have been made both at home and abroad, few of them can completely meet the need of protecting miner in above imminently hazardous situations. Therefore, it is extremely important and urgent to design a new type of mine safety helmet (Huang H R 2000, Jiang X R 2010).

On the bases of original mine safety helmet and against imminently hazardous situations that threaten head and face of miners, through theoretical calculation and material selection, designing system of a kind of airtight oxygen supplying safety helmet for mine emergent hedge was put forward (Jin P L 2001). Through actual experiment, anthropometric indicators were got when the safety helmet was worn, and characteristics of the safety helmet were known. Through simulating oxygen supplying methods by adopting FLUENT, the optimal oxygen supplying method of the safety helmet was finally designed out. This research can provide idea and reference for other relating researches, and can offer certain technical support for safe development of mines.

2 CHARACTERISTICS OF TRADITIONAL SAFETY HELMETS

As a tool to protect head, a safety helmet shall meet the following conditions in respects of design and structure:

1. Weight: the material adopted to make the helmet should be as light as possible and has enough strength so that it can stand assault of falling objects. Weights of helmets of small-size edge, medium-size edge and roll edge should not exceed 430 g, weight of a large-size helmet should not exceed 460 g, and weight of a cold-proof helmet should not exceed 690 g (weight requirements above do not include additional components).
2. Comfort: the helmet should be comfortable to wear, ensuring that wearers don't feel muggy even under sunshine.
3. Vertical spacing: vertical spacing is the axial distance between the highest point of head top and the inner surface of cap shell when the helmet is worn. Proper vertical distance should be 25~50 mm.
4. Horizontal spacing: when the helmet is worn, the horizontal spacing between cap hoop and each surface of cap shell should be 5~2 mm.

5. Wear height: when the helmet is worn, the axial distance between bottom edge of cap hoop and the highest point of head top should be 80~90 mm.
6. Size of cap hoop: size of cap hoop should be in either one of three ranges which are respectively 51~56 mm, 57~60 mm and 61~66 mm.
7. Size of brim: the minimum size of brim is 0 mm, and the maximum size of brim is 70 mm. Inclination of brim should be 0°~60°.
8. Size of visor: the minimum size of visor is 10 mm, and the maximum size of visor is 70 mm.

There are two current standards of safety helmet in our country which are GB2811-2007 *safety helmet* and GB/T2812-2006 *safety helmet test method*.

There are relevant standards about safety helmet around the world, such as USA ANSIY89. 1-1997, Canada CAN/CZA-Z94.1 and so forth (Sheng H T 2011).

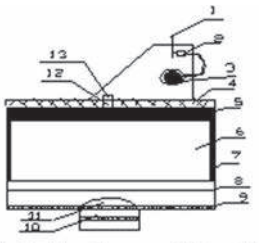
3 THE DESIGN OF SAFETY HELMET FOR MINE EMERGENCY HEDGE

On the original basis, a protective cover was added beneath brim of the helmet so that in case of danger, through releasing it, a confined space could be formed at head position of wearer and eye vision of wearer could be assured as the protective cover was made of transparent adiabatic material, and at the same time, oxygen could be automatically produced in internal space for a while.

Requirements of choosing material to make safety helmet for mine emergency hedge are as follows: firstly, a confined space can be formed to protect wearer's face; secondly, eye vision of wearer can be ensured and wearer's eyes also can be protected. Therefore, aluminium foil coated flame-retardant cotton cloth material was chosen against the first requirement, PVC (Polyvinyl Chloride) was chosen against the second requirement.

This safety helmet for mine emergency hedge can supply oxygen by an oxygen candle which is activated by a fire cap. Schematic diagram of the oxygen candle structure is shown in Fig. 1 (Zhang Z H 1995, Zhang G P 1991):

The appearance and structure of the safety helmet are shown in Fig. 2–Fig. 4.



4 PERFORMANCE EXPERIMENTS OF THE SAFETY HELMET FOR EMERGENCY HEDGE

4.1 *Experimental purposes*

Through carrying out anthropometric indicator experiments on the designed helmet, temperature, pulse, carbon dioxide concentration and some other parameters were measured when the helmet was worn so that theoretical basis can be provided for follow-up research on oxygen supplying method.

4.2 *Experimental apparatus and methods*

Main experimental apparatus include safety helmet, safety cover, dry bulb thermometer, wet bulb thermometer, thermocouple thermometer, stopwatch, gas chromatograph and so on.

1—trigging bezel; 2—blow hammer (firing pin); 3—spring; 4—adiabatic board; 5—trigger drugs; 6—oxygen candle;

Figure 1. Schematic diagram of the oxygen candle structure.

Figure 2. The 3D effect graph.

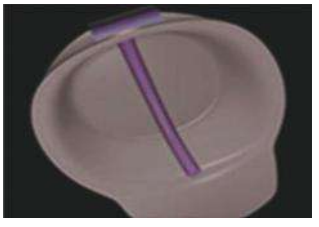


Figure 3. Arrangement of oxygen candle and vessel.

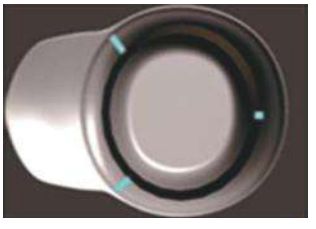

Figure 4. Fixed mode of down part of the helmet.

Experimental methods are as follows: a few 25-year-old healthy men were chosen to wear the helmet, and four measuring points respectively numbered T1, T2, T3 and T4 were respectively arranged at top of head, the front of head, the back of head and face position. As outside temperature was kept steady, parameters such as temperature, pulse frequency, carbon dioxide concentration and some others were measured at the four measuring points respectively within 5 minutes in the following three circumstances: stillness, walking and running.

4.3 *Experimental results and analysis*

1. Temperature variations of measuring points in the three circumstances
   Temperature variations of measuring points in the three circumstances are respectively shown in Fig. 5–Fig. 7.

   As shown in Fig. 5, under condition of stillness, temperature at each measuring point rises gradually and changes relatively fast from the first to second minute, but becomes steady from the third to fifth minute. Temperature at T4 keeps the highest and rises fastest, because T4 is measuring point at the face position inside the helmet where heat produced by breathing gathers. Temperatures at T1, T2 and T3 are similar.

   As shown in Fig. 6, under condition of walking, temperature at each measuring point rises gradually, and temperatures at T1, T2 and T4 change relatively fast from the first to second minute. From the third to fifth minute, temperature at T1 becomes steady, but temperatures at T2 and T4 keep on rising. Temperature at T3 stays at about 31.7 °C. Temperature at T4 keeps the highest because more heat can be produced by breathing under condition of walking. Temperature at T2 keeps the second highest because certain amount of heat can be diffused by the head under condition of walking.

   As shown in Fig. 7, under condition of running, temperature at each measuring point rises gradually, and temperatures at T2 and T4 rise fastest up to 39.1 °C, because more heat can be diffused by the head and much more heat can be produced by breathing under condition of running. Temperature at T1 rises to 35.4 °C within the first minute and becomes steady from the second to fifth minute. Temperature at T3 stays at about 35.5 °C.
2. Pulse frequency in the three circumstances
   As shown in Fig. 8, wearers can keep a normal heart rate for 5 minutes without extra oxygen supply in the three circumstances.
3. Concentration of CO_2 in the three circumstances
   As shown in Fig. 9, in the three circumstances, concentration of CO_2 produced by human is proportional to time. The maximum permissible concentration of CO_2 in air is 25000 PPM. Therefore, oxygen should be supplied in the helmet within 2 minutes.
4. Temperature variation at each measuring point
   As shown in Fig. 10, temperatures at T2 and T4 rise faster than that at T1 and T3. At T1, T2 and T3, differences of temperatures under condition

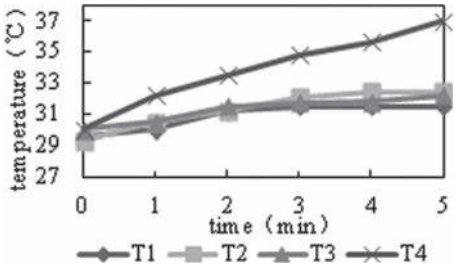

Figure 5. Temperature variation under condition of stillness.

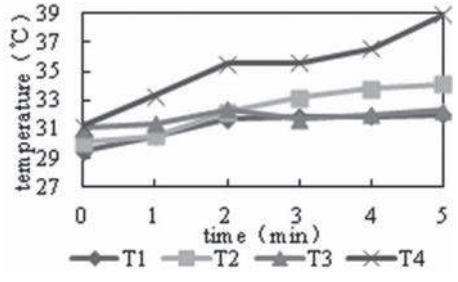

Figure 6. Temperature variation under condition of walking.

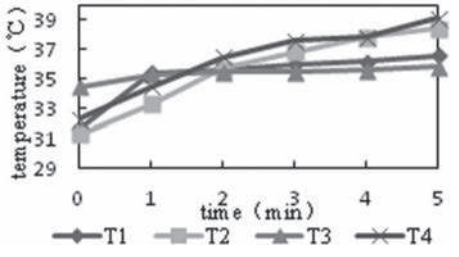

Figure 7. Temperature variation under condition of running.

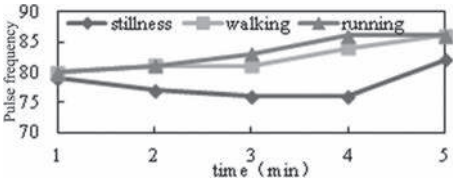

Figure 8. Pulse frequency in the three circumstances.

of stillness and walking are commonly less than 1 °C, but temperatures under condition of running are commonly more than 3 °C higher than temperatures under condition of stillness at these three measuring points. Temperature at T4 rises fastest in the three circumstances, because T4 is measuring point at the face position inside the helmet where more heat can be produced as breathing amount increases.

5 DESIGN OF OXYGEN SUPPLYING METHOD OF THE SAFETY HELMET FOR EMERGENCY HEDGE

5.1 *3D model of the safety helmet for emergency hedge*

The helmet was seen as a sphere with radius 10 cm, the hood was seen as a cylinder with height 10 cm and mask radius 10 cm. According to anatomical structure of head, thickness of head tissue and thermal influence, head was seen as a cylinder with radius 4 cm and height 10 cm, and windpipe was seen as a cylinder with radius 1 cm. After comprehensively considering heat generated by the safety helmet during experiment and possibilities of setting up oxygen supplying air-duct, three designing programs of air-duct were put forward as shown in Fig. 11 (Han Z Z et al. 2004).

Based on oxygen supplying flow being 1 L/min, radius of import tube being 1 cm and oxygen supplying speed being 10 cm/s, three models were respectively designed as follows: (a) supplying oxygen downward at top of head and making air flow out from the bottom; (b) supplying oxygen vertically at the front of head and making air flow out from the bottom; (c) supplying oxygen horizontally at the front of head and making air flow out from the bottom.

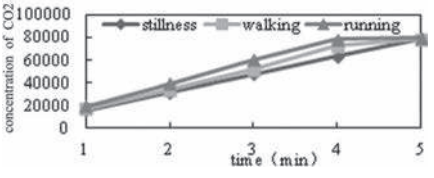

Figure 9. Concentration of CO_2 at T4 in the three circumstances.

5.2 *Design of oxygen supplying air-duct of the safety helmet for emergency hedge*

Through numerical simulation with FLUENT, wind speed at air inlet was set to be 10 cm/s, and environmental temperature and inlet air temperature were all set to be 298k. The bottom was set as pressure outlet and pressure was set as the

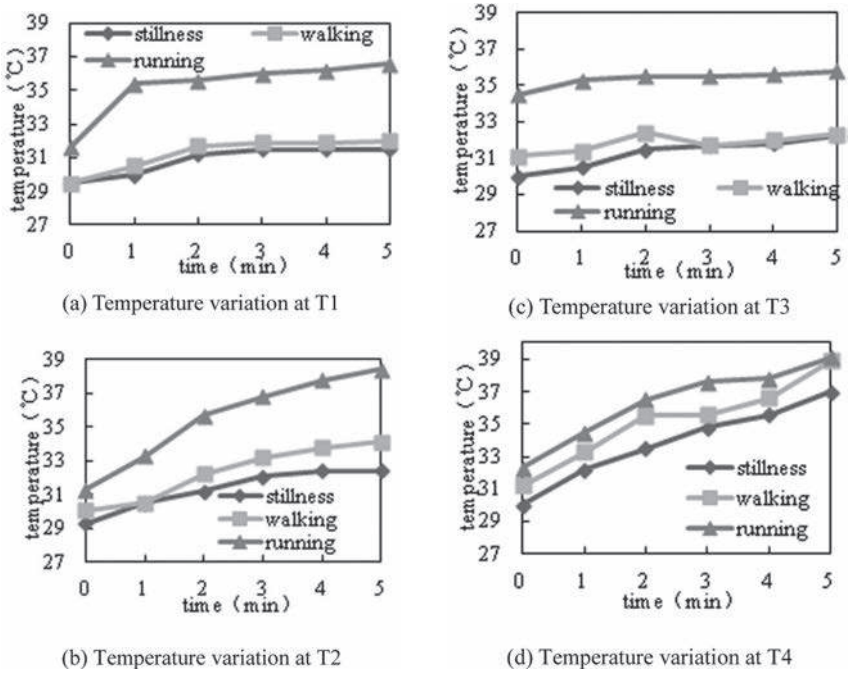

Figure 10. Temperature variation at each measuring point.

standard atmospheric pressure. Without considering influence of time, steady flow was adopted to simulate the three oxygen supplying methods above. Results of numerical simulation are shown in Fig. 12–Fig. 14.

What can be known from Fig. 12– Fig. 14 is that through supplying oxygen vertically at the front of head and making air flow out from the bottom, temperature rises slowest in the mask, and oxygen fully gathers at the face position, meeting the requirement. Therefore, this kind of oxygen supplying method should be chosen when designing oxygen supplying air-duct of the helmet.

5.3 *Design of oxygen supplying speed of the safety helmet*

Although it had been known that the best ventilation—cooling effect can be got by supplying oxygen vertically at the front of head and making air flow out from the bottom, the optimal oxygen supplying speed still needed to be further studied.

As temperature at air inlet was fixed to 298k, temperature distributions of the helmet when oxygen supplying speed was respectively 8 cm/s, 10 cm/s and 30 cm/s were got and shown in Fig. 15~Fig. 17.

(a) Supplying oxygen downward at top of head

(b) Supplying oxygen vertically at the front of head

(c) Supplying oxygen horizontally at the front of head

Figure 11. Three methods of air supply.

As shown in Fig. 15~Fig. 17, when oxygen supplying speed increases from 8 m/s to 10 m/s, temperature drops from 308k to 302k significantly; however, when oxygen supplying speed increases from 10 cm/s to 30 m/s, there is no obvious temperature change.

As temperature at air inlet was fixed to 298k, wind speeds at the face position in the helmet when oxygen supplying speed was respectively 8 cm/s, 10 cm/s, 30 cm/s and 50 cm/s were got and shown in table 1.

From Table 1, it can be seen that when oxygen supplying speed is 10 cm/s, wind speed is 0.0361 m/s. As oxygen supplying speed continues to increase, wind speed at the face position turns higher and higher. When oxygen supplying speed is in range of 10 cm/s~30 cm/s, effect of temperature dropping is not obvious, and high oxygen supplying speed makes wearer feel uncomfortable, moreover, amount of oxygen candle increases with oxygen supplying speed increasing, therefore, oxygen supplying speed of the safety helmet should

Figure 12. Temperature distribution while supplying oxygen downward at top of head.

Figure 13. Temperature distribution while supplying oxygen vertically at the front of head.

Figure 14. Temperature distribution while supplying oxygen horizontally at the front of head.

Figure 15. Temperature distribution when oxygen supplying speed is 8 cm/s.

Figure 16. Temperature distribution when oxygen supplying speed is 10 cm/s.

Figure 17. Temperature distribution when oxygen supplying speed is 30 cm/s.

be controlled at about 10 cm/s which can meet the need of supplying oxygen and dropping temperature at the same time.

6 CONCLUSIONS

1. A new kind of safety helmet for mine emergency hedge has been designed based on original miner's helmet. On the one hand, appearance and structure of the safety helmet has been designed to achieve the purpose of protecting wearer's face in case of danger; on the other hand, oxygen candle has been selected to provide oxygen, guaranteeing wearer's breath and safety.

Table 1. Wind speeds at the face position.

	8 cm/s	10 cm/s	30 cm/s	50 cm/s
Wind speed at the face position (m/s)	0	0.0361	0.1	0.2

2. The regularity of temperature changing inside the helmet has been got. As time develops, order of temperature from largest to smallest is temperature at the face position, temperature at the front of head, temperature at the back of head and temperature over the head. The highest temperature at the face position is 39.1 °C, and pulse frequency of wearer keeps at 77 times/min. Concentration of CO_2 inside the helmet reaches the critical value of 25000 PPM within 2 minutes under condition of no oxygen supply, which shows that the helmet can only ensure safety of wearer for 2 minutes.
3. The optimal oxygen supplying method has been optimized by numerical simulation. The best ventilation-cooling effect can be got by supplying oxygen vertically at the front of head and making air flow out from the bottom. And the optimal oxygen supplying speed is got to be 10 cm/s which can meet need of supplying oxygen for wearer and reducing weight of oxygen candle at the same time.

The research of dynamometer for anchor cable in mine tunnel based on the industrial Ethernet

Xuezhe Li, Xiaoping Li, Haimei Feng & Junming Liu
North China Institute of Science and Technology, Beijing, China

ABSTRACT: The traditional dynamometer for anchor cable has disadvantages of low precision, poor anti-interference ability, measurement results cannot be uploaded automatically, the comprehensive analysis of measurement results is difficult. In the paper, a dynamometer for anchor cable based on industrial Ethernet is proposed. The paper also introduces the principle and implementation of system project. It has the core of STC12C5A single-chip microcomputer, and realizes the accurate measurement of anchor stress condition by using fine torque measurement module, and realizes the data communication and sharing by using RTL8019AS Ethernet control chip. The sensor can monitor the status of anchor stress condition real-time and also can make pre-caution to the possible production accident.

1 INTRODUCTION

The analysis of anchor cable stress condition in mine tunnel is an important content of tunnel monitoring. Dynamic observation of anchor cable stress state is significant to the verification of roadway supporting effect, the monitoring of mine pressure regularity, and guarantee the safety of mine production (Wu 2007). At present, some dynamometers for anchor cable based on different principles have been developed at home and abroad. These instruments solves the problem of the coal mine pressure monitoring in a certain extent, but they generally also have some disadvantages of high cost, low precision, poor anti-interference ability, inconvenient installation and maintenance, these deficiencies limit their further development in the area of coal mine. In recent years, the technology of industrial Ethernet is developed rapidly, and has been widely used in coal mine area (Li 2010). In view of the characteristics of industrial Ethernet technology and the current situation of roadway cable force measurement technology, a dynamometer for anchor cable based on industrial Ethernet technology is designed in the paper. The sensor is designed by STC12C5A single-chip microcomputer and RTL8019AS Ethernet control chip. It realizes the monitoring of anchor stress condition real-time and reliably. And then through the Ethernet interface, the measurement results will be automatically uploaded to underground fiber ring network. The monitoring computer can directly receive the results and achieve storage, computation and analysis of the data. It greatly improves the precision and efficiency of detection.

2 PRINCIPLE AND SCHEME OF THE SENSOR

2.1 *The operation principle of the sensor*

The dynamometer for anchor cable is mainly composed of a torque measurement module and an instrument body. When measuring, the torque module is installed between the anchor plate and the fastening nut, and the nut is screwed by the spanner. Then the stress value of anchor cable is converted to a 0~5V voltage signal through the torque measurement module, according to the sampling voltage value, the instrument body achieves the analysis and calculation of anchor cable stress condition. Finally, the ground monitoring computer analyses the calculation results, which are uploaded through the Ethernet communication circuit. The installation diagram of dynamometer for anchor cable is shown in Figure 1.

2.2 *The technical scheme of the sensor*

The dynamometer for anchor cable designed in this paper composes of power supply circuit, CPU

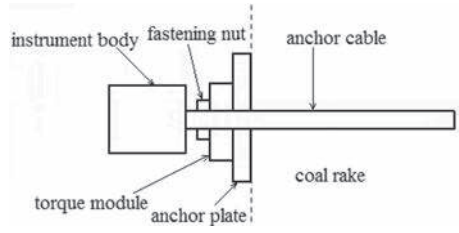

Figure 1. The installation diagram of sensor.

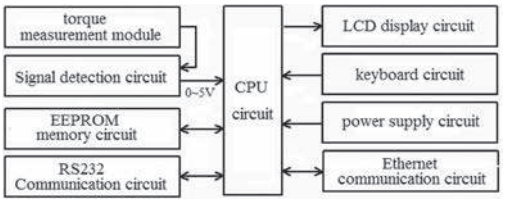

Figure 2. Structure diagram of dynamometer for anchor cable.

circuit, Ethernet communication circuit, signal detection circuit, LCD display module, keyboard module and torque measurement module. System structure diagram shows as Figure 2. Single chip microcomputer is designed by STC12C5A, which implementates functions of keyboard input, LCD display, anchor cable stress value detection, Ethernet communication chip control etc. STC12C5A60S2 is a high efficiency controller, which has advantages as follow, the technology is mature and reliable, the speed and precision of ADC is high, the price is low, its hardware and software resources can meet the design requirements (Chen 2010). The detection of anchor stress condition is achieved by fine torque measurement module, with the corresponding amplification and adjustment circuit. The module has the advantages of high precision, stable and reliable performance, compact structure, waterproof and dustproof, easy to use. Ethernet control chip is designed by RTL8019AS, which is a mature technology and widely used network control chip produced by Realtek Corporation. In addition, the sensor is also designed with the keyboard, LCD display, EEPROM memory circuit, which accomplish functions of sensor calibration and parameter display.

3 HARDWARE CIRCUIT DESIGN

3.1 *The design of CPU circuit*

CPU circuit consists of power module, CPU, reset circuit, clock circuit and program debugging download circuit. In this system, CPU is designed by STC12C5A60S2, whose main role is to execute AD conversion, process and display the sampling results, control Ethernet communication chip etc. The CPU circuit diagram is shown as Figure 3. The emphasis of CPU circuit design is pin function definition. In this system, P0 is used as the data interface, which is connected with the 8 bit data bus of RTL8019AS. P2 is responsible for data bus simulation of LCD screen; P1 achieves functions of LCD control, keyboard input and AD sampling, wherein WY1 is used for detecting of anchor cable stress value; P3 and P4 are responsible

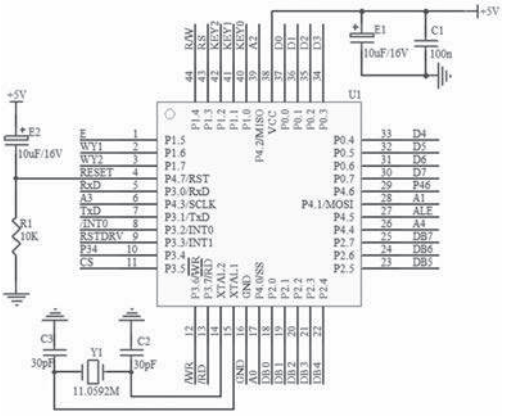

Figure 3. CPU circuit schematic diagram.

for the simulation of RTL8019AS control signals and address signals.

3.2 *The design of anchor cable stress detection circuit*

In the system, the detection of anchor stress condition is achieved by fine torque measurement module, with the corresponding amplification and adjustment circuit., the circuit schematic diagram shows as Figure 4. The detection circuit is based on full bridge strain acquisition circuit and high accuracy, low drift operational amplifier of AD620, which not only eliminates the temperature drift and nonlinear error of strain gauge, but also can obtain higher sensitivity and accuracy. The transfer function of the signal detection circuit is: $Q_P = K \times \Delta U_1 + B_0$, wherein Q_P is the anchor force value, K is the proportional coefficient, B_0 is the compensation constant (Shi 2000). These constants can be determined by calibration method. SCM can easily calculate the cable force according to the sampling voltage and the transfer function.

3.3 *The design of Ethernet interface circuit*

In the system, the network control chip adopts RTL8019AS, which is produced by Realtek company. The connection of key signal in the circuit is designed as follows:

1. Data bus mode setting: 8019AS has 8 bit and 16 bit two data bus mode, which is selected by pin of IOCS16B (96 pin). In the system, we set the mode of 8 bit data bus by connecting IOCS16B to ground through a 27 K resistor.
2. I/O base address settings: I/O base address of 8019AS chip is setted by pins of IOS0~ IOS3 (pins 81, 82, 84, 85). In the circuit, we set the address of 300H by connecting IOS0~IOS3 to ground.

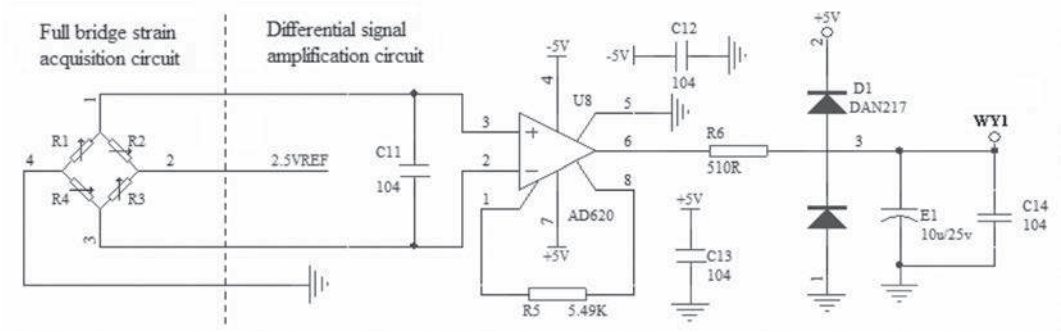

Figure 4. Anchor cable stress detection circuit schematic diagram.

3. Hardware configuration setting: In the design, pin of JP (65 pin) is connected to power 5V, which set the hardware configuration mode for the jumper mode. The jumper mode, when 8019AS chip resets, CPU will read the state of each jumper pin, and save as the initial configuration of the system default.
4. 8019AS reset design: we control the RTL8019AS chip reset by MCU P3.3, which is connected with reset pin of RSTDRV.
5. Data and address bus design: In 8 bit data bus mode, P0 of MCU is used as the data interface, which is directly connected with 8 bit data bus SD0~SD7 of RTL8019AS; The address range of internal registers and memory of 8019AS is 00H~1FH, the I/O base address has been setted to 300H, thus addressing range of address bus is 300H~31FH. In the system, the low 5 address bits SA0~SA4 of 8019AS are directly connected to low 5 bits of P4 of MCU, SA8 and SA9 are controlled by the chip select signal CS.

3.4 *The design of user interface*

In order to facilitate the users, achieve the calibration and display of parameters, system is designed with keyboard and display module. Using the general matrix keyboard with interface circuit, we can conveniently select the function and input parameters. Using LCD screen, we can display cable force real time. The key interface is designed by 74HC148, and the LCD screen is designed by LCD1602.

4 SOFTWARE DESIGN

4.1 *Software overview*

The software of the dynamometer is designed by C language, we use the KeilC51 platform to complete the establishment of project, compile, program download. Software includes: main program module, keyboard input module, LCD display module, parameter calibration module, cable force measurement module and Ethernet communication module etc. SCM first display the boot information on the LCD screen, then according to the hardware settings, respectively, into the "calibration" and "measurement" mode. In "calibration" mode, SCM acquires calibration curve under the control of keyboard, which provides reference data for the precise measurement of cable force; In "measurement" mode, SCM collects, calculates and displays the measurement results, meanwhile uploads the results to fiber ring network through the Ethernet interface, then the monitoring computer achieves further analysis and processing. System software main program flow diagram is shown as Figure 5.

4.2 *The design of Ethernet communication software*

The design of Ethernet communication software is very important in system software design. Following is a brief description of the key software modules.

1. Design of RTL8019AS initialization modules: RTL8019AS initialization involves registers CR, PSTART, PSTOP, TPSR, BNRY, CURR etc (Zhou 2003). The initialization process is shown in Figure 6.
2. Design of data transmission module: When transmitting data packets, SCM writes data in the specified format into the chip and starts sending commands, then RTL8019AS automatically converts data into physical frame format for transmission on the physical channel.
3. Design of data receiving module: When receiving data packets, RTL8019AS automatically restores the physical signal received to the data, and stores the data in the specified format in

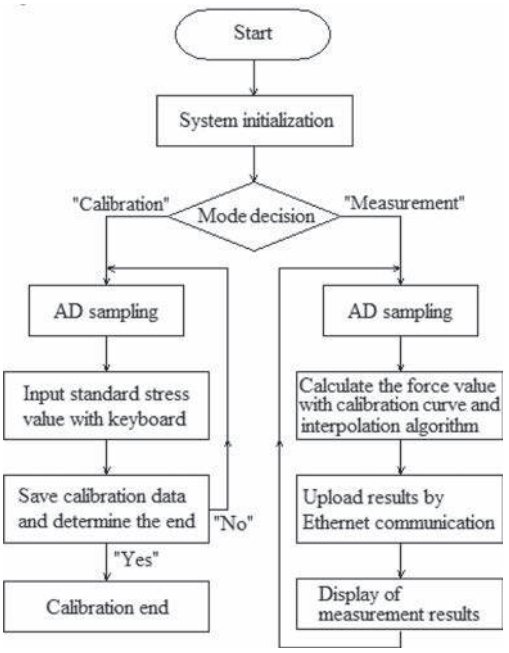

Figure 5. System software main program flow diagram.

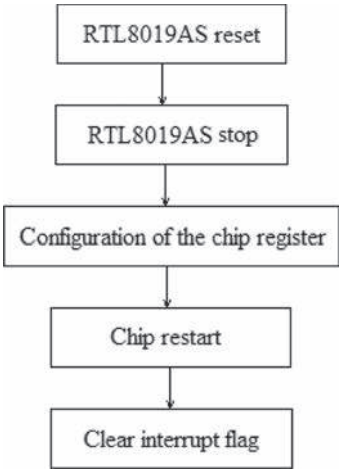

Figure 6. RTL8019AS initialization flow diagram.

RAM, then SCM can read data from RAM and complete the corresponding function.

4. Design of register read-write module: SCM realizes the chip initialization, physical address setting, data packets receiving and transmitting by controlling the RTL8019AS internal registers and DMA port, these functions are achieved through the register read-write module.

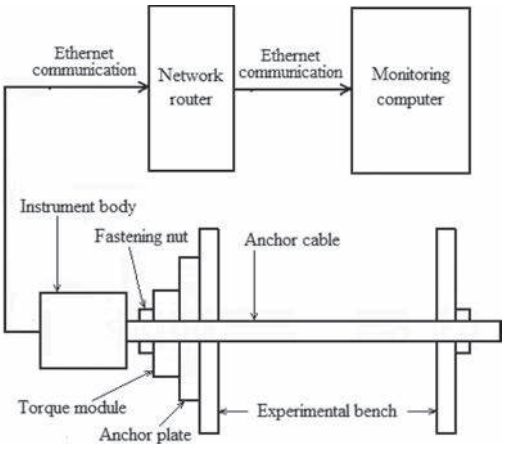

Figure 7. Experimental diagram of the dynamometer.

Table 1. Experimental result of the dynamometer.

Index	Standard tension (KN)	Sampling voltage (V)	Measurement tension (KN)	Error (KN)
1	10	0.48	9.9	0.1
2	20	0.72	19.8	0.2
3	50	1.51	48.8	1.2
4	100	2.79	98.1	1.9
5	150	4.15	147.2	2.8

5 EXPERIMENT AND ANALYSIS

Aiming at the dynamometer for anchor cable designed, we do the experiment on WDW-300 microcomputer control electronic universal testing machine, the experiment is schematically shown in Figure 7. The testing machine provides standard stress signal in fixed step of 10 KN; SCM records the voltage value corresponding with each stress point automatically, then calculates the actual stress value of anchor cable; The computer obtains the measurement results from the dynamometer through Ethernet interface. The experimental data are shown in Table 1. Experimental results show that the dynamometer designed in the paper can achieve precision measurement of anchor cable stress value, the error is limited within ± 2.5%; The sensor can upload the measurement results flexibly through Ethernet communication, can meet the requirements.

6 CONCLUSION

In this paper, a dynamometer for anchor cable based on industrial Ethernet is proposed, which

involves the computer control technology, modern sensor technology, Ethernet technology, and has advantages of high precision, high efficiency, low cost and flexible control. Innovation of this paper is fully integrated hardware and software advantages, design and implement a high precision, full-automation dynamometer for anchor cable, which provides a new technical means for ensuring safety production of coal mine.

Research on safety lead-acid battery charger in coal mine

Quan-Zhu Zhang
North China Institute of Science and Technology, Sanhe, Hebei, China

Ming-Yan Xu
Anhui University of Science and Technology, Huainan, Anhui, China

ABSTRACT: Around global development goals and needs of the coal mine safety production in our country, and solving the key scientific and technological problems about security of mining safety electrical equipments to strengthen the management of mine power supply equipments and establish safe and reliable power supply system. Charging unit is the important electrical equipment matched with lead-acid storage battery in coal mine, its good or bad performance directly affects the running reliability of lead-acid battery. This paper designed a set of mine safety intelligent lead-acid battery charger, it not only solved the problems of common battery charger and also provide effective protection for charging process. So it can meet the needs of actual production.

1 INTRODUCTION

Safety is the eternal theme in coal mine production, is the important guarantee for realizing safety production, the core of coal mine production is to realize high production and high efficiency on the basis of safety. Practical experience tells us: only setting up the concept that coal mine safety is the highest efficiency of business, it can be advantageous to realize the organic unity of both efficiency and security. Safe production is the important guarantee for sustainable, stable and healthy development of our country mining industry, with the development of social economy, safe production more and more highlights its important position and role. Mine battery electric locomotive (Bai, et al 2007) is a major transport device for coal mine production, mainly driven by DC motor at present. Aiming at common faults of lead-acid storage battery in mine battery locomotive, the paper introduced a set of mine safety intelligent charger (Liang & Zhang 2006), it used advanced switching power supply technology and intelligent control technology, not only improve charging efficiency, but enhance charging reliability and not producing any harmful gases in the charging process. The charger has characteristics such as light weight, small volume, high efficiency, good control performance, and protection functions for over-voltage, under-voltage, over current, overload, battery voltage detection and polarity, at the same time it achieves the whole process of tracking management and health diagnosis for equipment use and maintenance to provide quick and efficient material guarantee for coal mine safety production.

2 STRUCTURE OF THE SAFETY CHARGER

The security smart charger (Li 2009) has only one cavity including main circuit, control circuit, detection circuit and drive circuit, the structure diagram is shown in Figure 1, the back of control device is equipped with external radiator system mainly for power device (Su 2009) heat leak. In order to realize high efficient and safety charging for lead-acid storage battery, the charger used the charging way of constant current in early stage and constant voltage in later stage to avoid large charging current for constant voltage charging in early stage and over-charging phenomenon for constant current charging in later charging, on the basis of the monitoring,

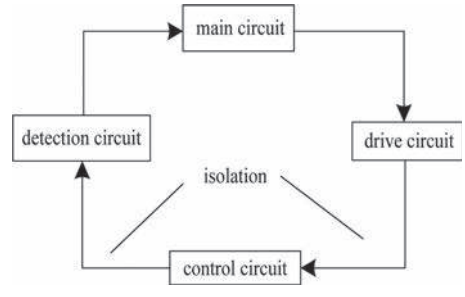

Figure 1. The installation diagram of sensor.

it carried on the management and control for storage battery, more conducive for the maintenance of battery and prolong the battery life. Battery charger charges for storage battery on the one hand and completes the management for the battery on the other hand. Control circuit provides the real-time detection for charging voltage and current and gives alarm indication for abnormal situation, stops output to protect the battery at the same time. Battery charger provides battery condition monitoring unit that provides real-time acquisition, storage and records for single battery in the process of charging, then implements the functions of information ground transmission through the USB interface, with mating battery ground software analysis system for analyzing storage batteries including working condition of all single batteries and judging timely the poor section of single battery to remind the maintenance staff to timely replacement of batteries. In addition, it uses output contactor and detection control to realize the battery polarity protection. The design of charging system adopted high frequency switching power supply technology, the main circuit consists of three-phase bridge rectifier circuit, IGBT single-phase high-frequency inverter circuit, high frequency transformer, single-phase full bridge high frequency rectifier circuit and filter circuit. Main circuit used IGBT as the power device master, continuous adjustment of output voltage and output current is achieved by IGBT single-phase inverter, it adopts the PWM control mode.

2.1 *Control circuit design*

Control system of the charger (Wang 2006) is mainly composed of control signal generating part, signal acquisition part, drive part, system protection part, function setting part and status display parts, they real-time exchange data and information among them through the CAN bus, the system block diagram is shown in Figure 2, each component has a reasonable allocation fully guaranteeing the accuracy and reliability of the system control. The control system design combined with the advantages of good steady state performance for voltage loop control and the advantages of improvement for current loop control system dynamic performance, the control object is output voltage and output filtering inductance current. Control circuit used the digital integrated circuit device, highly integrated to the control circuit of the machine. Control system used single chip processor as the core, through the acquisition of status information, such as battery terminal voltage, temperature, and charging current, after modulus conversion in sampling circuit, these signals are sent into the single chip microcomputer for proceeding analyzing and processing to generate corresponding control signals for switching device IGBT in main circuit and the charge and the discharge circuit. It finally realized intelligent charging by adjusting output voltage and current through double loop ratio control, at the same time the control system monitored various parts of the main circuit and temperature of IGBT to play a very good protection effect for charging system and realize the battery quick green and charging. The charging device (Zhang 2009) has a good human-machine interface, charging parameters and state can be displayed on digital tubes, operates conveniently and has a good reliability.

2.2 *Fault detection of the charger*

IGBT inverter bridge consisting of power electronics device works in the switch state, and susceptible to instantaneous peak voltage, short

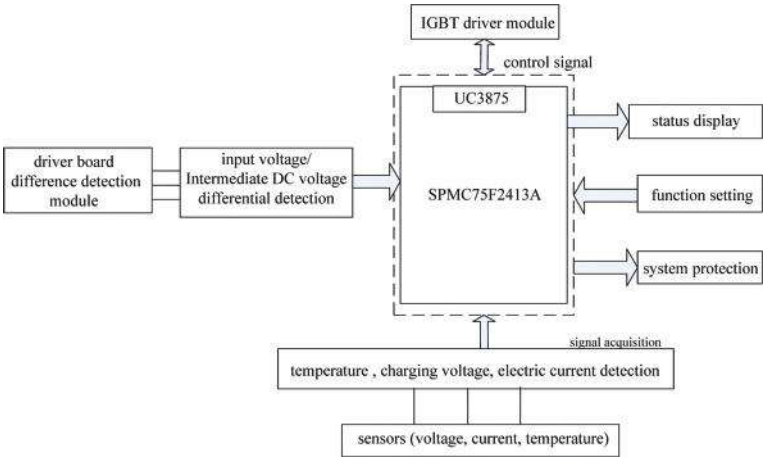

Figure 2. Control system diagram of the charger.

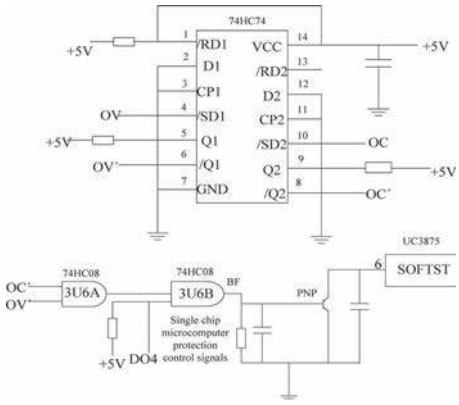

Figure 3. Protection circuit diagram.

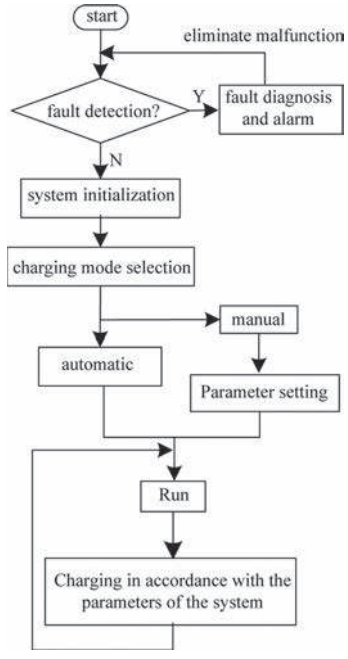

Figure 4. Main program flow chart of charging.

circuit current, instantaneous direct connection and overload for the arm up switch tube and down switch tube caused by instantaneous phase PWM signal chaos, it often leads to abnormal operation of the circuit and burns semiconductor devices of the bridge arm. So, the device joined the corresponding protection circuit to guarantee that switch components will not be damaged due to the circuit fault, and improve the safety and reliability of the device. UC3875 offers the input signal for SOFT-START, it is used to conveniently realize all kinds of protection function of inverter system. Concrete implementation block diagram is shown in Fig. 4. Output of fault signal through 74HC74 latch does comprehensive setting by gate 74 HC08, then connected to a foot of UC3875 (Zhu 2010) soft start through PNP triode. The use of latch prevents the misoperation caused by interference signal and makes the protection action more reliable.

3 SOFTWARE DESIGN OF CONTROL SYSTEM

A charger with a superior performance should not only have good hardware system but have a good software system. The design idea of the main program for charging is that charging scheme of the design is constant current charging and constant voltage charging, it implements automatic conversion for different charging stages and real-time shows charging status and alarm function for achieving the purpose of quick charging and prolonging storage battery recycling. The software of charger adopts the modularized program design method, charging flow chart is shown in Figure 4. The charger did a fault detection in internal after power on, if found abnormity, it displayed fault type and location and eliminated the fault to identify the system is normal, only then can the system initialize. System initialization procedures included the I/O port initialization, event initialization, ADC initialization, timer initialization, etc. Charging mod selection is mainly made users select of charge mode according to the state of storage battery including automatic charging and manual charging. Manual charging does real-time operation according to the characteristics of the storage battery. Parameter setting is mainly used for a variety of charging parameters including starting current, stop charging pressure, park voltage. Battery started charging when not pressing the pause key. Program flow char of external fault interruption is shown in Figure 5, if found defective signals during the process of charging, they will real-time display, at the same time, the system immediately clear the fault signals in order to ensure the charger to work normally.

Battery voltage, current and temperature did real-time monitoring throughout the charging, detective signals sent to single chip microcomputer for processing to control open and shut off of IGBT to achieve the fast charging strategy.

4 RESULTS AND DISCUSSION

The collected voltage waveform of the safety mine lead-acid battery charger is shown in Figure 6 and

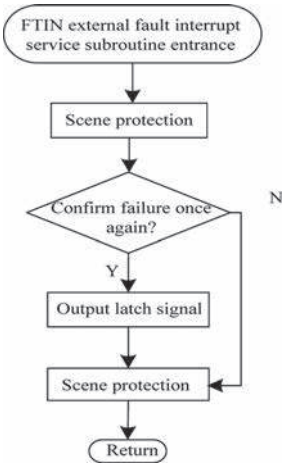

Figure 5. External fault interrupt program flow chart.

Figure 6. The collected voltage waveform of the charger.

Figure 7. The collected voltage waveform of the charger.

Figure 7, the waveform is basic consistent with theory waveform but existing some high frequency interference, considering the influence of high frequency transformer used in the charger, and the interference is within acceptable range.

5 CONCLUSION

Technological innovation is to promote the progress of enterprise technology and the development of enterprises, Coal technology innovation to really play to the role of the first productivity, while safety is the stability of coal industry, the fundamental guarantee of sustainable, rapid development, is the relationship between coal mine worker's life safety and physical and mental health, relationships, loss to the state and collective property from a top priority. Coal technology innovation should really play the role of the first productivity, and security is the fundamental guarantee for stability, sustainable and rapid development of coal industry, is a top priority about the relationship between coal mine worker's life safety and physical and mental health, not loss of national and collective property. So Coal mining technology innovation must conscientiously implement the Party's production policy of "safety first". With the development of China's coal and the requirements of safety situation, use information technology to transform traditional coal industry, rely on advanced management concept and use a variety of modern information and automation technology. Design aim of the Mine safe intelligent charger is to provide comprehensive and systematic theory and technical support and is of great significance to promote coal mine safety production.

Studies on the large capacity mine lithium ion battery intelligent charger

Z. Quan-Zhu, S. Xiao-Lei, D. Yong-Hong & M. Hong-Mei
Information and Control Technology Institute, North China Institute of Science and Technology, Beijing, China

ABSTRACT: Combined with the security problem of the charging of mine large-capacity lithium ion battery, the author puts forward a reliable scheme of the lithium-ion battery charger. In this paper, the key structure and function of the charger are introduced and analyzed, the parameter of the phase-shifting chip UCC3895 are designed and optimized, the authors also introduces the MAX11068 battery management chip's application in the charger, which can quickly and safely complete the charging process of the large capacity lithium ion batteries. The promotion and application of the large-capacity lithium ion battery is of great significance in the coal mine security production.

1 INTRODUCTION

Different from the past lithium ion battery, the large-capacity lithium ion battery is over 3 Ah generally. To reach high battery capacity and voltage for the device, the lithium ion batteries should be connected in series and parallel in practical applications. At present, the application of the large-capacity lithium ion battery in some place and equipment such as movable life-saving cabin, refuge chamber, mining electric locomotive and dust vehicle is already in research phase. The popularization and application of the large-capacity lithium ion battery in coal mine production at home and abroad is seriously constrained by the battery's security. Due to the drive of the national "863" major projects and electric vehicle market, the study of large-capacity lithium ion battery in green electric vehicle power has began (BI 2008), however, its application as power in the mine electrical equipment or other mining equipment is almost blank because of the lack of corresponding standards, security charging and BMS technology. Now the lead-acid batteries, small capacity, short lifetime and against environment protecting, are most commonly used in production of coal mine. If they can be replaced by the large-capacity lithium ion batteries, this will greatly save the production costs and improve coal mine production environment. Large-capacity lithium ion battery should be charged in cycle constantly in applications, then to design a safe charging scheme is of great significance to the popularization and application of large-capacity lithium ion battery in coal mine safety production. Combining security features of the large-capacity lithium ion battery with former scholar' research, the authors puts forward a safe charger scheme of the large-capacity lithium ion battery.

2 SECURITY PRECAUTIONS OF LITHIUM ION BATTERY CHARGING PROCESS

Lithium ion battery is strict with voltage, current and temperature whether in charging or discharging, which should be controlled strictly in the process of charing (WANG 2005). Some primary notices as follows:

3 LITHIUM ION BATTERY CHARGING PROCESS

Lithium ion battery charging process is divided into two stages: constant current fast charging and constant voltage slow charging. In the first stage, the voltage of the battery rises all the time, immediately transferred to the second stage as soon as the voltage reaches the settings. Current weakens to the settings gradually along with the battery rising to finish charging. To the first charging of the battery, the time should be as long as possible (generally three or four hours), so that the electrode oxidize as completely as possible. The initial charge mode run once every so often, in order to achieve maximum releasing of the battery's capacity.

The scheme selects eight strings battery pack SE60AHA (monomer's nominal voltage is 3.2 V). At first we should charge the battery fast in constant current mode (≤1CA), then start slow charging when it reaches to constant 24 V (plus or minus 50 mv less). Stop charging until the battery is full or start tiny current charge according to the actual situation. This constant current mode followed by constant voltage should take about two hours to charge the battery fully.

4 FUNCTION REALIZATION AND RESEARCH PRIORITIES

Shown in Figure 2, the intelligent charger mainly consists of four parts: AC/DC main circuit, DSP control part, the output sampling part and lithium ion batteries management. Work as follows: input mine voltage AC 380V/50 Hz or AC660V/50 Hz, after inverter, rectifier, inverter and filtering, output controllable DC voltage and current to the batteries by controlling the IGBT off and on. In this process, the IGBT's temperature, the output and input value of the voltage and current are transformed to the controller DSP by the sampling circuit to complete the closed-loop control and protection (ZHANG 2009). Lithium ion battery's equalization control, collection and protection of voltage and temperature are completed by the BMS chip MAX11068. The emphasis of this scheme include IGBT inverter control technology, voltage and current double closed-loop and BMS technology.

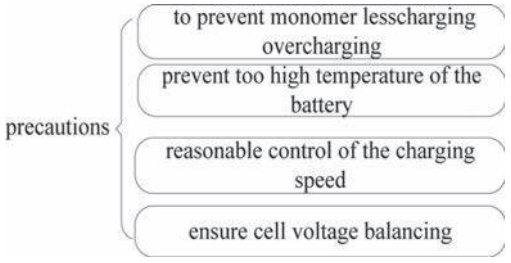

Figure 1. Rechargeable lithium-ion battery pack precautions.

4.1 *Setting of IGBT inverter PWM signal parameter and the output of experimental waveform*

The achievement of the output of the voltage and current double closed-loop control are completed mainly by adjusting the PWM pulse signal, which could control the IGBT's off and on, generated by the chip UCC3895. On the basis of theoretical analysis and experimental verification, the parameters of the chip are optimized and adjusted. Shown in Figure 3, UCC3895 uses average current control mod, which has high noise inhibiting ability, no slope compensation, and widely used in the PWM control circuit (Mihail 2012). Then the input of the error amplifier noninverting is voltage control signal V_+, the input of the inverting is the inductor current signal V_- in the end. Output of the Error amplifier tracks error signal, the signal is compared with the saw tooth signal of the RAMP pin to obtain PWM, as the IGBT's driving control signal. The CS pin is overcurrent end, whose turn-off voltage is 2.5 V and its input signal is inductor current signal. When an overcurrent or short-circuit occur, it can immediately turn off the PWM output, the large-capacity lithium ion battery can be well protected against overcurrent and damage when charging. The SS pin to the ground through a capacitor can achieve soft-start function, the experimental output waveform shown in Figure 5.

The setting of Frequency: $f_{out} = f_{in}/2$. f_{out} is the frequency of the four outputs, f_{in} is the internal clock frequency of the chip, then the t_{osc} can be calculated. In order to get the output frequency of 20 kHz, f_{in} = 40 kHz, C_T = 100 pf, which can be calculated by the chip clock cycle:

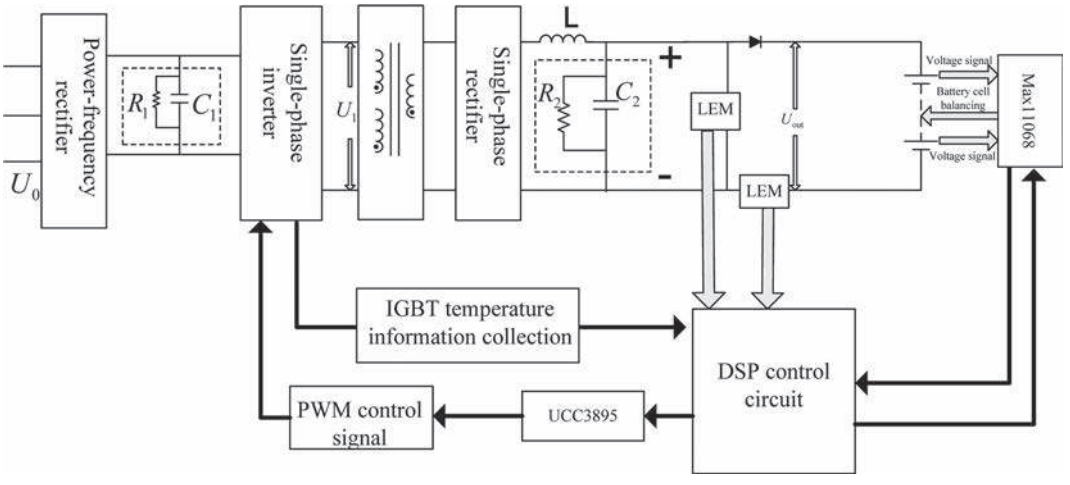

Figure 2. Lithium-ion battery smart charger main circuit topology.

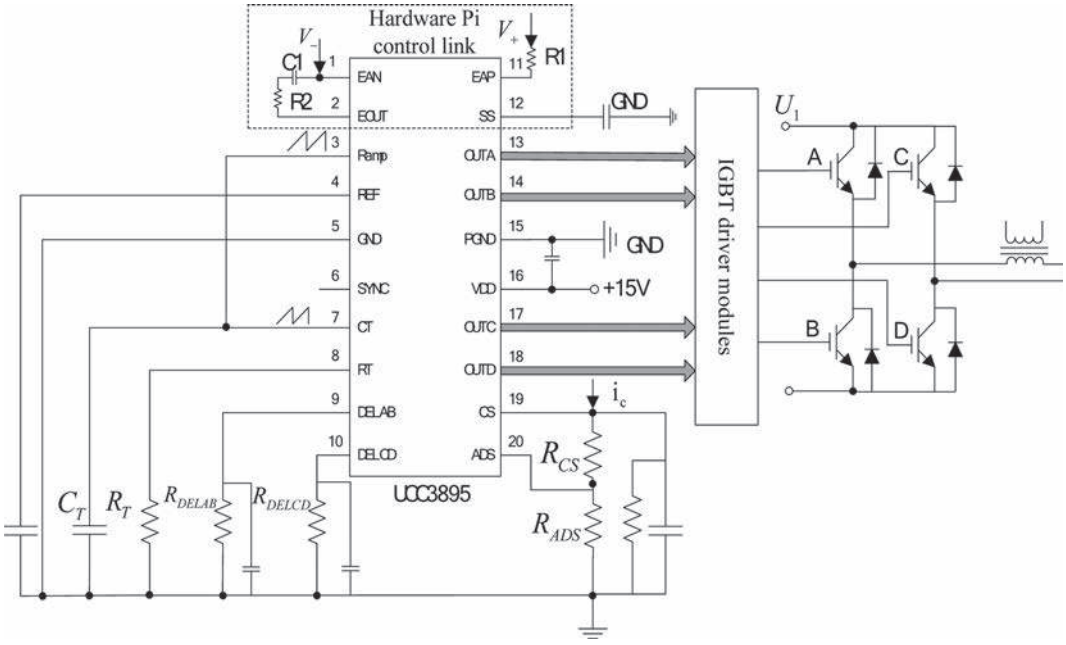

Figure 3. UCC3895 drive the IGBT topology.

$$t_{osc} = \frac{5R_T C_T}{48} + 120ns \quad (1)$$

The setting of the delay time $T_{DELAY:}$

$$t_{DELAY} = \frac{25\times10^{-12} R_{DEL}}{V_{DEL}} + 25ns \quad (2)$$

The output delay time, the voltage V_{DEL} across the DELAB and DELCD meet:

$$V_{DEL} = 0.75\times(V_{CS} - V_{ADS}) + 0.5\text{v} \quad (3)$$

The range of the '$V_{CS} - V_{ADS}$' is 0V ~ 2.5V. The range of the V_{DEL} is 0.5V to 2.375V, the output current size must meet:

$$I_{DEL} = \frac{V_{DEL}}{R_{DEL}} \le 1mA \quad (4)$$

Selected the R_{DELAB} = R_{DELCD} = 109 kΩ, R_{CS} = 200 kΩ, R_{ADS} = 100 kΩ, in this case:

I_{DEL} = 0.016 mA < 1 mA.The range of dead time T_{DELAY} is 1.15us ~ 5.45 us.

4.2 *The double close-loop control*

The control of the charger output choose the double close-loop control mode: outer voltage loop, inner current loop. The output waveform can be well fitted for the lithium-ion battery charging wave form (the maximum error is 50 mV), as shown in Figure.6, which plays a very large role in improving the efficiency of the battery and extending its life. Inner current loop is set by software, the outer by UCC3895. peripheral circuit shown in Figure 5 hardware PI modulation link.

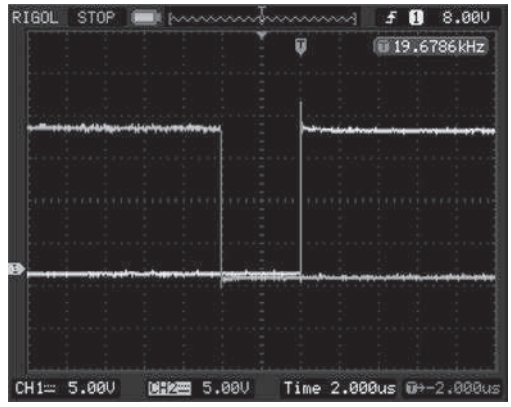

Figure 4. OUTA and OUTB output waveform, T_{DELAY} = 4 us.

Initial charging began with the constant-current mode outputting, K1 is off, K2 is closed to the b side, the internal error comparator of the UCC3895

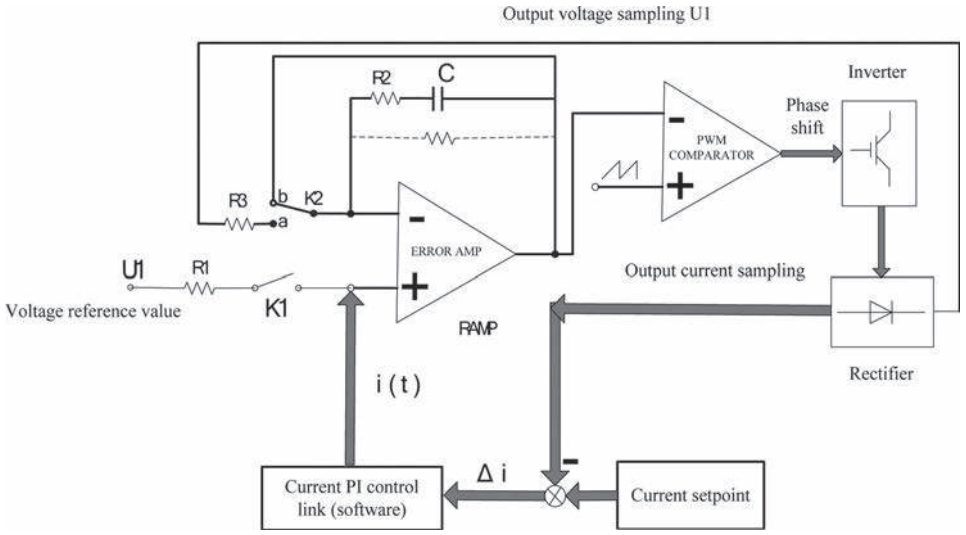

Figure 5. Voltage and current structure diagram.

is wired as follower, enter the current closed loop control mode, the K_I, K_P of the current loop is set by software. The relation ship between the input and output is:

$$i(t) = K_P \Delta i(t) + K_I \int_0^t \Delta i(t) dt \tag{5}$$

In constant current mode, the voltage of the battery will continue to rise with the conduct of the charging process. In the current loop, in order to maintain the constant current, the output voltage of the charger will continue to rise, and always maintains a certain pressure difference. Immediately transfer to the voltage closed-loop control in constant voltage mode, when the charger output voltage rise to the reference value U1, K1 is opened and K2 is closed to the a side, R1 is equal to R3 in it. The input-output relationship:

$$u(t) = -\frac{R_2}{R_3} e(t) - \frac{1}{R_3 C} \int e(t) dt \tag{6}$$

$$e(t) = U_1(t) - U_2(t) \tag{7}$$

With the decreasing of the pressure difference in the constant voltage mode, the output current continue to decrease to certain rules when the current is reduced to 0, then the battery is fully charged, the charger stop charging or continue to trickle mode charge (WANG 2004).

4.3 *BMS of large capacity lithium ion battery*

Because the majority BMS of the lithium ion battery at home has complicated control strategy,

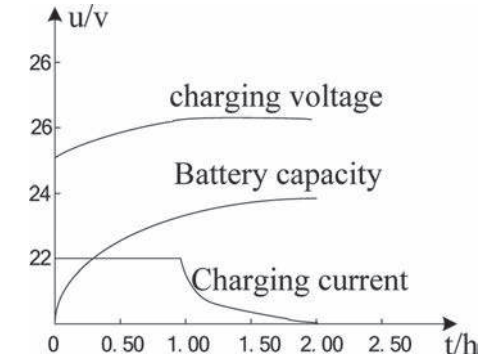

Figure 6. Rechargeable lithium-ion battery pack equalization waveform.

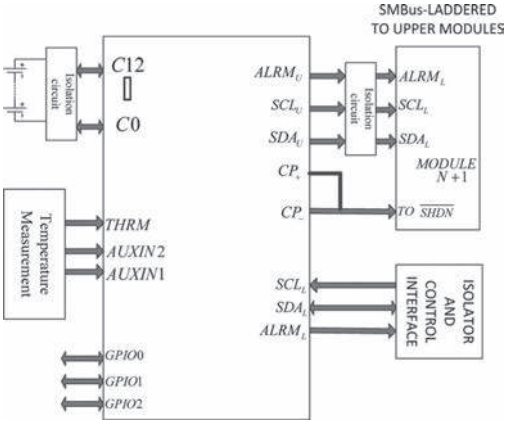

Figure 7. MAX11068 work topology.

large volume and high cost, it can't be applicated in the mine (LEI 2010). The MAX11068, BMS IC produced by TI solve these problems very well. It have great temperature detection, overvoltage and undervoltage alarm function, and can make active voltage balance.

5 CONCLUSIONS

The mine charger of the large-capacity lithium-ion battery put forward by the author can use AC 380 V 50 Hz or AC 660 V 50 Hz to charge the battery fast and safely. Inversion use the IGBT power modules, which has fast responsetime, 25 kHz inverter frequency. The PWM control pulse signal is formed by UCC3895. The chip has excellent over-current protection and soft start function which can protect the circuit so well though the whole charging process, the double closed-loop control is also completed by this IC. In addition, the BMS use the latest BMS IC, MAX11068, which can save cost and improve the security in using the lithium ion battery. Based on the demand and problem in the high-capacity lithium battery charging, the author put forward a reasoned and safe charger design of the large-capacity lithium-ion battery.

The structural optimization and numerical simulation of wet centrifugal precipitator in fully mechanized heading face

Hai-Fei Yao
Mine Safety Technology Branch, China Coal Research Institute, Beijing, China
State Key Laboratory of Coal Mining and Clean Utilization, China Coal Research Institute, Beijing, China

Ping-Jun Hu
Henan Dayou Energy Co., Ltd., Yima, Henan, China

ABSTRACT: For the characteristics of driving working face of chinese coal mine, designing three types of structural model of wet centrifugal precipitator. In order to optimize their internal structure efficiently, three types of structural physical model are established and meshed by Gambit 2.2. Solving containing dust airflow three-dimensional velocity distribution in the precipitator, static pressure field distribution, the characteristics of turbulent flow field; the move track of different size of dust in the precipitator by Fluent 6.2. Simulation results showed that shunt plate plays an important role in separating airflow. It can make the movement of vortex steady, besides, maintaining the continuity and stability of high-speed airflow, the symmetry of static pressure distribution, the regular change of turbulent kinetic energy; steady flow field and high speed centrifugation are critical to remove respirable dust. The precipitator which contains shunt plates and two rows of baffle in the middle (Model three) have advantage in maintaining air flow velocity and the changement of turbulent kinetic energy compared with the one which contains shunt plates and three rows of baffle in the middle (Model one), however, two die areas take place in the front of the first baffle, which reduce the collection efficiency. Through the above-mentioned aspects of the general comparison, choosing the structure of model one as the production model of precipitator.

1 PREFACE

As pre-open working face of mechanized mining, mechanized heading face produce large amount of dust, which is only less than mechanized mining. Because of the characteristic of multi-process, dust dispersion and high degree of dust dispersion, mechanized heading face become the focus of dustproof (Jin et al. 2001, Wang, X.Z et al. 2001).

At present, the dust control measures in mechanized heading face mainly is inside and outside the spray of boring machine, air curtain, wet dust, spray in reproduced point, water curtain in roadway, etc. However, some disadvantages may take place in practice: first, we usually apply the ventilation mode of active pressure wind and passive wind, spray in mechanized heading face, transform face airflow into air mist easily, which may affect the sight of the worker and bring a serious hidden danger; second, The above measures don't control the airflow, therefore, collection efficiency is relatively low (Jin 2001). Precipitators are used widely in Some of the major coal-producing countries, but dust equipment abroad generally large in size and didn't apply in our country's roadway (Dong et al. 2006), therefore, it's important and significant to develop precipitator which is suited to China's coal mines.

We will establish three internal structure physical models of wet centrifugal collector by Gambit 2.2 in this article, and then meshing. Solving three-dimensional velocity distribution, static pressure field distribution, turbulence characteristics of flow field of dust-laden air, the move track of different size of dust in the precipitator by Fluent 6.2. So as to choose optimal model.

2 MATHEMATICAL MODE

2.1 *Gas equations*

Gas flow in flow field can be described by Navier-Stokes equations, and then close equations by revised turbulent fluctuation RNG k-ε two-way model, dealing with wall flow by wall function method (Wang et al. 2004). The model reflect the impact of small-scale through viscosity which is got after large-scale motion and amendments, remove small-scale movement systematically from

equations. k equation and ε equation is similarly to the standard k-ε model.

$$\frac{\partial(\rho k)}{\partial t}+\frac{\partial(\mu k u_i)}{\partial x_i}=\frac{\partial}{\partial x_j}[\alpha_k \mu_{eff}\frac{\partial k}{\partial x_j}]+G_k-\rho\varepsilon \quad (1)$$

$$\frac{\partial(\rho\varepsilon)}{\partial t}+\frac{\partial(\mu\varepsilon u_i)}{\partial x_i}=\frac{\partial}{\partial x_j}\left[\alpha_k \mu_{eff}\frac{\partial \varepsilon}{\partial x_j}\right]+\frac{C_{1\varepsilon}^{*}\varepsilon}{k}G_k-C_{2\varepsilon}\rho\frac{\varepsilon^2}{k} \quad (2)$$

Where, k and ε are unknown quantity, ρ is density of fluid (kg/m^3), μ is fluid dynamic viscosity coefficient, $\alpha_k = \alpha_\varepsilon = 1.39$, G_k is item of turbulent kinetic energy k which was produced by average gradient, u_i is time-averaged velocity (m/s), $C_{1\varepsilon}^{*}$, $C_{2\varepsilon}$ are empirical constants.

Compared with standard k-ε model, the main change of RNG k-ε model is (Shih, T.H et al. 1995): First, through revising turbulent viscosity, consider rotation and swirling flow during the average flow; Second, adding one item up to ε equation, reflect average strain rate of mainstream E_{ij}, so the produce items of RNG k-ε model not relevant to the situation of flow, but a function of space coordinates in the same question. Therefore, RNG k-ε model can deal with high strain rate and large streamline curvature of flow (Pan, X.Q & Yuan, J. 2004).

2.2 *Discrete phase model*

Solving discrete phase particle track under particle effect balance equation of lagrangian coordinates. The form of particle effect balance equation under cartesian coordinate system (x direction) is (Morsi, S.A. & Alexander, A.J. 1972):

$$\frac{du_p}{dt}=F_D(u-u_d)+\frac{g(\rho_p-\rho)}{\rho_p}+F_x\mu \quad (3)$$

Where, u_p is particle velocity (m/s), FD $(u - u_d)$ is quality drag force of particle (N/Kg), u is fluid phase velocity (m/s), μ is fluid dynamic viscosity coefficient, ρ_p is particle density (kg/m^3), F_x is other forces in x direction.

3 PHYSICAL MODEL AND BOUNDARY CONDITION

3.1 *Set up physical model*

The whole model is divided into nine sub-block by GAMBIT software, then meshing, physical model and mesh division are showed in Fig. 1. considering

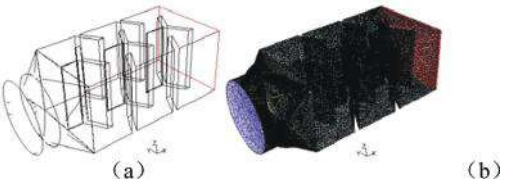

Figure 1. The physical model and mesh of precipitator. (a) The physical model of precipitator; (b) Meshing of precipitator.

Table 1. The set of various types of value.

Boundary conditions		Define
Inlet Velocity Magnitude		23.6 m/s
Hydraulic Diameter		0.6 m
Turbulence Intensity		2.87%
Outlet Boundary Type		Outflow
Wall	DPM Condition	Trap
	Shear Condition	No Slip

calculation and simulation of numerical simulation, this article simplify model from the following aspects: gas is incompressible; parameters of gas flow change little as time, so consider gas flow as unsteady flow; consider the gas-solid flows, replace effect of liquid film sticky with simplify trap boundary condition; Suppose wall of precipitator insulation, ignore heat transfer between the gas-particle and the wall.

3.2 *Set boundary condition*

The set of various types of value are showed in table 1.

In the process of calculation, determine flow field whether arrive at convergence according turbulent kinetic energy, turbulence dissipation rate, velocity and residual of continuity equation (Han, Z.Z et al. 2004, Fan, J.R et al. 2001). Suppose residual of the above physical quantity is 1.0×10^{-3}, flow field arrive at convergence in this numerical simulation.

4 SIMULATION RESULTS AND ANALYSIS

4.1 *Simulation and analysis of airflow field in precipitator*

To choose the best model, this article will study the velocity, pressure field, distribution law of turbulent kinetic energy among the precipitator which contains shunt plates and three rows of baffle in the middle (Model one), the one contains no shunt plate and three rows of baffle in the middle (Model

two), the one contains shunt plates and two rows of baffle in the middle (Model three), As shown in Fig. 2.

4.1.1 *Simulation and comparison of the speed variation*

Z = 0 axial cross section velocity vector of three models of precipitator are shown in Fig. 3.

As can be seen from fig. 3, in the course of removing dust, the velocity of air flow become higher and higher, the maximum speed mainly take place near baffle, especially on the edge of baffle, the minimum speed take place in the export. the velocity of air flow get smaller first and then progressively larger from entrance to export, which caused by the change of x axis cross-sectional area of precipitator, Because the airflow which was sucked in precipitator is steay, when it comes to the edge of baffle, area suddenly reduced, the velocity of air flow increase. Except for high-velocity zone in precipitator, there are 10 main vortexs which lies behind vertical filter, the two adjacent vortex form vortex pairs at the same time.

The feature line which is formed by linking point (0, 0.25, 0.2) and point (1.8, 0.25, 0.2) is shown in Fig. 4, the change of velocity of three models in feature line is shown in Fig. 5.

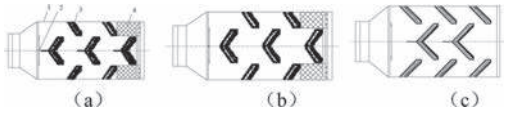

Figure 2. Vertical view of wet centrifugal precipitator. 1—the body of precipitator; 2—nozzle; 3—vertical gas-liquid filter; 4—flat gas-liquid filter; (a) model one; (b) model two; (c) model three.

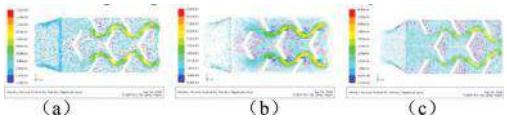

Figure 3. Velocity vector of z = 0 axial cross section. (a) model one; (b) model two; (c) model three.

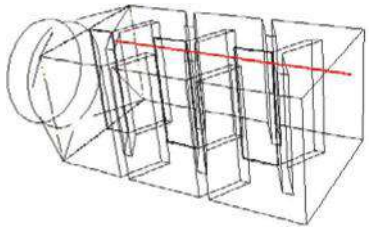

Figure 4. The location of feature line.

Compared with model one, because of lack of shunt plate, movement of vortex pairs of model two is very unsteady, which will influence the continuity and stability of high-speed airflow, through velocity is swifter; because of the change of filter layout, the distance between the first filter and entrance extended segment become small, the vortex make the first filter nearly useless, which cause the velocity of air flow reduce about 1/3.

4.1.2 *Simulation and comparison of static pressure distribution*

Z = 0 axial cross section static pressure distribution nephogram of three models of precipitator under rated operating conditions are shown in Fig. 6.

As can be seen from fig. 6, Local high-pressure zone exists both sides of the shunt plates, which is beneficial to form a stable, continuous high-velocity zone, so compared with figure (a), the symmetry of pressure distribution in figure (b) (c) is poorer. The three models' static pressure drop in feature line are shown in fig. 7, The static pressure

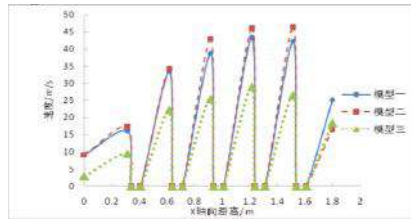

Figure 5. The velocity distribution of three models in feature line.

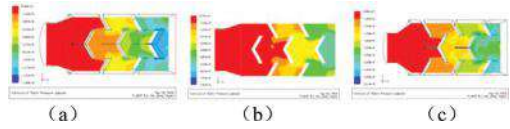

Figure 6. Static pressure distribution nephogram of z = 0 axial cross section under rated operating conditions. (a) model one; (b) model two; (c) model three.

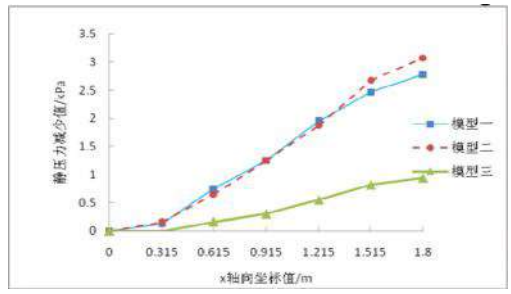

Figure 7. Static pressure distribution of three models in feature line.

drop of model three is significantly lower, It can be seen that the filter layout way is the main factor that affects the flow field. After the comparison between speed change and the symmetry of static pressure distribution, from the aspect of maintaining flow stability and static pressure distribution symmetry, model two is poorer than model one and three, so we can give up model two and only analysis model one and three in the following article.

4.1.3 *Simulation and comparison of turbulent kinetic energy distribution*

Z = 0 axial cross section turbulent kinetic energy of precipitator under rated operating conditions are shown in Fig. 8.

As can be seen from fig. 8, turbulent kinetic energy contour change from thin to dense, reach maximum in the tail of precipitator. Because of viscidity on the wall of precipitator, which will create velocity gradient and eddy, turbulent kinetic energy is bigger on the wall and the baffle. The vortex on outer wall boundary layer move fast, driving movement of the inner vortex, receiving the energy of turbulent vortex from the mainstream (Xu J. & Ge M.C. 1998, Wang, H.G et al. 2004, Zhou, G.J. & Yan, Z.Y. 1992). Comparing Figure a and Figure b we can see that Z = 0 axial cross section turbulent kinetic energy of model three is disorder and random. This shows that the change of turbulent kinetic energy is unstable, which will cause air speed and air resistance impermanence, it isn't beneficial to remove dust stable and efficient and the safe of mechanized heading face.

4.2 *Simulation and comparison of dust trajectories in precipitator*

To choose better model from model one and three, this article make dust trajectories numerical simulation by the method of single-phase coupling, studing the move track of different size of dust under rated operating conditions. The direction of incident velocity plumb imported face of velocity, incidence velocity is same as inlet velocity, solid mass flow rate is zero, in order to observed trajectory, set source of jet is single-size dust, distributing

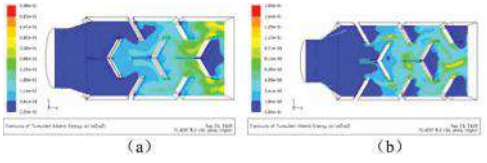

Figure 8. Turbulent kinetic energy of z = 0 axial cross section under rated operating conditions. (a) model one; (b) model two.

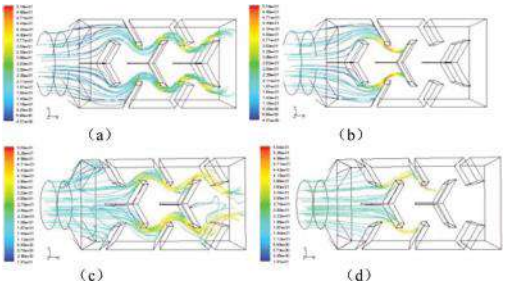

Figure 9. Dust trajectories in the precipitator. (a) Model one and dust particle is 7.07 μm;(b) Model one and dust particle is 30 μm; (c) Model three and dust particle is 7.07 μm; (d) Model three and dust particle is 30 μm

uniform in entrance section. This article only set 7.07 μm and 30 μm representative size for example. The dust trajectories of model one and model three are shown in Fig. 9.

As can be seen from fig. 9, incidence dust was divided into two parts uniformly and continue to move with air flow at the first shunt plate, trajectories is similar to "zhi"-shaped curve, incidence dust in the left of speed entrance turn left, incidence dust in the right of speed entrance turn right, all of these are due to the guide of airflow field.

Compared with (a) and (c) in Fig. 9, adding two low-speed zones in the front of the first baffle, which is called "dead zone" in engineering, "dead zone" isn't beneficial to separate gas and solid (Jones, W.P. & Launder, B.C. 1972), can't use space of precipitator effectively, reduce the efficiency of collection. Compared with (b) and (d), "dead zone" affect the dust size of 30 μm little, dust was trapped fully after the third baffle. in general, part dust in model three move disorder, but dust in model one move regularly.

Based on the above simulation and analysis, choosing model one as the last model of precipitator.

5 CONCLUSION

Through setting geometrical model and boundary condition, this article do gas-solid flow numerical simulation for wet centrifugal precipitator, analysis and compare the distribution law of velocity, pressure, turbulent kinetic energy of airflow field in three different precipitator, the dust move law of different sizes of dust under rated operating conditions, The results showed that:

1. Except for high-velocity zone in precipitator, there are 10 main vortex which lies behind vertical filter, the two adjacent vortex form vortex

pairs at the same time. There are local high-pressure zones on both sides of shunt plate, which is beneficial to form stable and continuous high-velocity zone, Compared with model one, the symmetry of pressure distribution in model two is poorer. There is high pressure zone before the first filter, the distrance between baffle and wall of precipitator is smaller, all of these may hinder the formation of vortex and cause the asymmetric of pressure distribution in the whole flow field.

2. Turbulent kinetic energy contour change from thin to dense, reach maximum in the tail of precipitator, Z = 0 axial cross section turbulent kinetic energy distribution of precipitator under rated operating conditions is very disorder, which isn't beneficial to remove dust stable and efficient and the safe of mechanized heading face.
3. Adding "dead zone" in the front of the first baffle in model three, "dead zone" isn't beneficial to separate gas and solid, can't use space of precipitator effectively, reduce the efficiency of collection. Based on the above simulation and contrast, choosing the precipitator which contains shunt plates and three rows of baffle in the middle (Model one) as the last model of precipitator.

ABSTRACT: The term warning sign which is clarified as it is typically applied to organization, to product, and particularly to workplace safety, is intended to alert persons to potential dangers in the environment and/or in the product. Warnings have become an important part of our modern lives not only because they provide essential information, but also because of constantly increasing regulations that require warnings to be present almost everywhere. During the past three decades, the body of empirical research on warning design and evaluation has grown in Europe and America. However, little research in this area has been delved in China. This paper reviews the literature on warning sign (safety/warning label included) and its effectiveness to support a reasonable, effective and cost-efficient approach to the design of warnings in China, especially in coal mine. There are now basic principles and guidelines for warning sign design and placement (using system approaches). Similarly, effectiveness evaluation (behavioral intention and behavioral compliance) have been developed. And, a series of researches and literatures have investigated several factors that determine safety sign compliance, including sign characteristics (salience, wording, size, layout and placement, pictorial symbols), personal factors (age, culture/ethnicity, gender, length of service, individual experience), situational factors (familiarity and training, risk perception, rewards and punishment, cost of compliance), organizational safety climate, (organizational environment, personal communication, administrative situations).

1 INTRODUCTION

Safety issue has been always the accompaniment during people using and maintaining a product or environment. Warnings are part of the interface between people and the surrounding (product and environment), which are intended to alert persons to potential dangers. Warning sign has been in applied in products and environments, including almost all industries. Warning signs are given in so many fundamentally different situations that the ways in which they are administered are very different as well.

During the past three decades, there has been a substantial, and increasing, amount of research on risk (safety) communications, more specifically, warning sign. The purpose of this article is to provide a review of the guidelines for warning design and evaluation based on empirical research and theory analysis in different industries. Through the review of the achievement, the warning sign design and evaluation can catch the scientific idea and method in China, especially in coal mine.

The design and evaluation of safety sign has received considerable attention by human factors/ergonomics researchers. These researches have encompassed both theoretical issues as well as application concerns, including a number of reviews and collections of the safety sign research literature. Two are collections of research articles from the Human Factors and Ergonomics Society (Laughery et al., 1994; Wogalter et al., 2001) (Laughery K. R., 1994; Wogalter and Young, 2001). A book by Edworthy and Adams (1996) (Edworthy and A, 1996) contained a general review of visual and auditory warnings. Other reviews published in the 1990s include Wogalter et al. (1995) (Wogalter and Barlow et al., 1995), Wogalter et al. (1999) (Wogalter and Young, 1999). More recent reviews are reported in Wogalter M.S. et al. (2002) (Wogalter and Conzola et al., 2002), Laughery K. R. and Wogalter M.S. (2011) (R. and S, 2011). Also, a substantial handbook that reviews the warnings literature has been published (Laughery, 1993; Wogalter et al., 2006; Wogalter, 2006) (Laughery and Wogalter et al., 1993; Wogalter, 2006; Wogalter and Silver et al., 2006).

Besides, there are lots of literatures about the specific application and research of warning sign in different industries, transportation, agriculture and medicine etc.. Among them is, such as Elliott M.A, et.al. (2003) (Elliott and Armitage et al., 2003) about warning sign of speed limits, Waterson, P. et al. (2012) (Waterson and Pilcher et al., 2012) about safety signs for children on board trains, Clack, Z.A et al. (Clack and Pitts et al., 2000) about warning sign of safety-belt using in transportation, Rother H.(2005)(Rother, 2005) about pesticide warning labels in agriculture, Huddle J.R et.al. (1991) (Huddle and Vanhoy et al., 1991) about warning sign for nuclear instruments in nuclear safety.

In this paper, the review and discuss of warning sign encompasses visual safety management, therefore, is limited to warning signs presented to the visual sense. However, during the safety communication process, there are common processing systems independent of the receiving modality, in other words, after the sensation experience, the later ones (the knowledge and compliance stages) are applicable regardless of the sensory modality that initiated it.

2 THE FUNCTION PRINCIPLE OF WARNING SIGN

Based on the relevant theory of safety field, the research detail and basic organization of the paper are explained.

2.1 *Relevant basic theory*

In the fields of safety, as well as in human factors and ergonomics, there is a basic set of strategies to prevent hazards from injuring people and damaging property, called the safety hierarchy or hazard control hierarchy (Sanders and McCormick, 1993). In the hierarchy, the priorities for dealing product or environmental hazards are: first is to design them out, second is to guard against them, and third is to warn.

The first and preferable approach to dealing with hazards is to eliminate them through an alternative design (such as substitution etc.). However, it is not always technologically and/or economically feasible to design out hazards. Guarding, the second priority, can be viewed as a means of preventing people from the hazard through time and/or space partition (such as installing interlocking device, reducing duration of exposure etc.). However, like the alternative design issues, guarding is not always practical or effective. A third technique of control hazards is to warn. As already referred, warning sign are intended to provide information to alert persons to potential dangers in the environment and/or in the product.

2.1.1 *Hazard and accident-causation theory*

It has been universally accepted that, hazard is the cause (root) of accident, that is to say, effective hazard control can prevent accident from occurring. According to GB13861-2009, hazard is categorized into four types: human, thing, environment, and management factors.

According to the modern accident-causation (G. and B. et al., 2005), from the point of individual behavior-safety control, hazard is embodied unsafe act (behavior) and unsafe condition; meanwhile, under certain situation, unsafe act (behavior) can transform and result in unsafe condition. The unsafe act and unsafe condition is the direct cause of accident, deeper analysis comes to the indirect (common) cause, which include three elements: inadequate safety knowledge, inadequate safety awareness, and inadequate safety habit.

It has been general agreement among researchers, and industry that individual (staff) unsafe behavior (act) is the elementary level in event (accident)-chain modeling, no matter in a simple system or in a sophisticated socio-technical system (Leveson, 2004). Thus, study on behavior safety is worthwhile. The accident-cause analysis is ranged in individual scope, i.e. not go further to organizational cause, which is addressed as the common cause of accident (see Fig. 1).

2.1.2 *Purpose of warning sign*

Warning sign is safety communication, and it is intended to communicate information about safety issues or problems. Its purposes can be referred to as safer world, provide information, influence behavior, and reminder, among which, the behavior influence is the effect issue, and that is to say, compliance behavior is the result of warning.

As the paper is a behavior-based study, it is focused on the issue of influence behavior. From this point of view, warning can be regarded as an effort to influence or control behavior, which concentrates on whether the behavioral intent of the warning is achieved. If the compliance behavior is

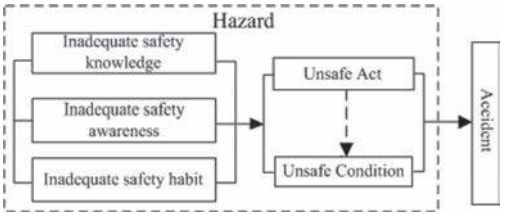

Figure 1. The common cause of accident.

achieved, the safe act is achieved to a large degree, and meanwhile, the unsafe act (unsafe condition) falls.

In the last analysis, the purpose of warnings is to make the world a safer place. In other words, reduced accidents and losses (injuries and damages) and improved safety and health would be goal for evaluating the effectiveness of warnings at this level.

2.2 *The function principle of warning sign*

Warnings and safety signs have three main purposes (Wogalter, 2006): firstly, to communicate safety related information so that people can make better, more informed decisions regarding safety issues; secondly, to persuade people to behave safely in order that their behavior helps to reduce or to prevent injury and health problems; and, thirdly, to remind individuals who may already know the hazards but may not be consciously aware of them at the time that knowledge is necessary (i.e., warning can recall pre-existing knowledge).

2.2.1 *The principle of warning sign to prevent accident*

From the engineering viewpoint, the primary reason to provide a warning is to reduce accidents (Lehto and Papastavrou, 1998). As effective warning sign is an important method to control hazard, and the elimination and reduction of hazard can prevent accident from occurring, the principle of warning sign to control to prevent accident is logical. To be specific, warning sign is set according to hazard identification (unsafe act and unsafe condition); and meanwhile, reasonable warning sign can eliminate and reduce hazard, and further prevent and reduce accident and loss. The principle of warning sign to prevent accident is shown in Fig. 2, which is also illustrative diagram of warning sign design, after all, the design of warning sign is aimed at accident-prevention and loss-reduction.

2.2.2 *The function principle of warning sign's effectiveness*

Warnings, like the other strategies can also be limited in effectiveness. As the visual warning sign,

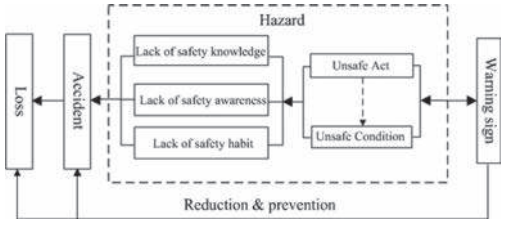

Figure 2. The principle of warning sign to prevent accident.

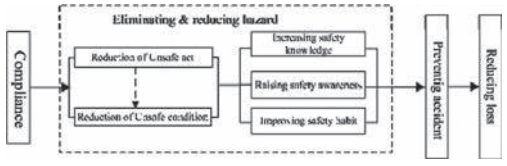

Figure 3. The function principle of warning sign's effectiveness.

people may not see, and/or they may not understand it, or they may not be sufficiently motivated to comply with it. Although these limits exist, far from not setting the warning signs where it is proper and required, these limitations mean warning sign deserve more attention to achieve better effect (Laughery, 2006). That is to say, it should be designed more attentively so that it is more likely to be effective. The parameters and elements needed during design will be explained later in the paper.

Then, the critical question arises, "Does warning work and how to evaluate whether it effect?"

That is issue of the effectiveness evaluation. As mentioned above, the compliance behavior (and/ or intent) is defined as the chief indicator to evaluate the effectiveness of warning sign in the article. The effectiveness is attributed to compliance behavior, because the compliance is in conformity with the idea of behavior control and behavior safety science, in which unsafe behavior contributes to almost all accident. That means, if people behave according to the correct directives and rules (warning sign), accident and loss can be prevented and reduced to a large degree. The function process of compliance is shown in Fig.3.

As safety communication, the effect of warning sign follows the information processing procedure. Therefore, this indicator (compliance) is a later stage in the communication procedure. A further discussion about other evaluating criteria and indicators and influencing factors will be made in the following paragraph based on literature-review.

3 DESIGN OF WARNING SIGN

As mentioned above in the article, from the engineering viewpoint, the primary reason to provide a warning is to reduce accidents. However, from a decision-making perspective, warnings may be ignored if they seem to be irrelevant to task performance. Another concern is that excessive warnings may result in information overload. Therefore, scientific design is significant for more intelligent and considerably more effective warning signs. So whether the regulatory requirements concerning warnings are satisfied by warnings is enough for a warning sign design, obviously no.

For example, most regulatory requirements very limited amounts of risk and emergency information, but, it is found that the effectiveness of warnings can be improved significantly by providing more information about the likelihood of the occurrence of the stimulus. It needs more thorough research to meet the demand of warning design.

The design is based on two typical theories or models, communications theory and human information processing theory. The typical, basic communication model has four components: the source, the medium, the message and the receiver (see Fig. 4).

The human-information processing framework is a stages model, consisting of stages through which warning information flows (see Fig. 5).

Generally speaking, in warning sign design, two aspects should be considered, design parameters of the warning sign, and characteristics of the target user (i.e. receiver) and situation. Design parameters include format factors such as wording, pictorial symbols, color/contrast, size, layout and placement, and content factors that should be expected to matter are explicit information considering hazards, consequences and conductions.

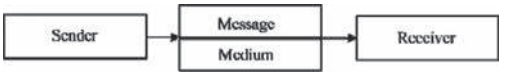

Figure 4. Basic communication model.

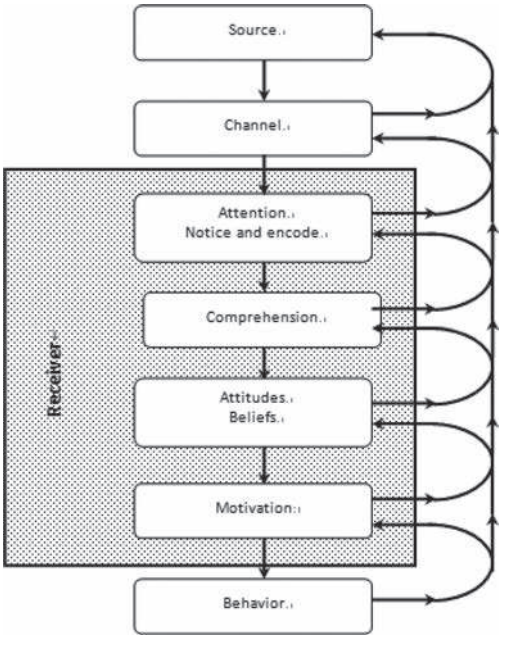

Figure 5. The C-HIP model.

3.1 *Salience*

Existing research indicates warning labels are generally ineffective due to users ignoring them(Rodriguez, 1991). And it has been found that salient warning sign increase the likelihood of reading, comprehension, recall and compliance (Braun and Mine et al., 1995; Glover and Wogalter, 1997; Hopkins and Parseghian et al., 1997).

Traditional researches focus the features of salience on size of the label, location, bold print, and pictorial symbols (Hussain and Arens et al., 1991; Kline and Braun et al., 1993; Braun and Mine et al., 1995) etc. Michael A. Rodriguez (Rodriguez, 1991) studied the combined effect of color, shape. Laughery, K.R (Laughery and Young, 1991) studied the principle of searching warning messages through eye tracking procedures.

3.2 *Design parameters and elements of warning sign*

3.2.1 *Wording*

Standards, guidelines, and research findings suggest that an effective warning sign should generally include four message components, signal word, hazard, consequence, and instruction statements (Young and Wogalter et al., 1995). It has a practical implication that word is the main form of expression message. For the first component, the most common used signal words are DANGER, WARNING, CAUTION, and NOTICE, successively connotes the degree of hazard from the greatest to the least. It is found that the presence of a signal word in warning sign increases its effectiveness and the level of perceived hazard(Wogalter and Jarrard et al., 1992; Wogalter and Brelsford, 1994; Young and Wogalter et al., 1995).

Secondly, warning sign should describe the potential hazard present in the situation. The hazard description should be specific and complete so that people can catch up the nature of hazard. It needs to notice that brevity should be considered as well as completeness.

Third, description of the possible consequences of non-compliance should be included. It has been cognizant of the importance of consequences information of warning sign in China. More explicit consequence description have been associated with greater levels of perceived dangerousness, hazard understanding, perceived injury severity, intent to act cautiously and protective equipment use (Dingus and Wreggit et al., 1993; Laughery and Vaubel et al., 1993; Braun and Silver, 1995; Ayres and Wood et al., 1998; Al-Madani, 2000; Clack and Pitts et al., 2000).

Finally, the warning sign should offer directives or instruction on how to avoid the hazard and how

to deal with the conceivable consequence when an abnormal incident occurs. In fact, instruction is hazard avoidance directives, which should describe specific actions that need to be taken (or avoided) by the warning recipient for safe behavior (act).

In a word, explicit information for all three warning content categories: hazard, consequences and instructions is of great importance. Explicit and overall information play a significant role in compliance (Laughery Sr and Paige Smith, 2006).

Figure 6. Representative warning designs used in China.

3.2.2 *Pictorial symbols*

Usually, the majority of people notice pictorial symbols at first glance at a warning sign. So it is not surprising that including pictorial symbols in warning sign increases their salience and likelihood of being noticed. An important function of pictorials is to facilitate warning comprehension. Comprehension is the degree to which the recipient understands the warning, based upon the intended meaning the warning is designed to convey.

A warning must first be legible (early stage of information processing) before it can be comprehended (later stage of information processing). However, it has been demonstrated that many warning symbols currently in use are poorly understood. To answer this issue, the American National Standards Institute (1998) standard ANSI-Z535.3 Criteria for Safety Symbols recommends the use of training to improve comprehension. Mary F. Lesch (2003; 2008) (Lesch, 2003; Lesch, 2008) has studied age-related differences and impact of training, and different training methods for improving warning symbol comprehension. It was found that training should be used to improve warning symbol comprehension since failures to adequately understand warning information may lead to injury or death, and relatively simple training conditions can dramatically improve accuracy and speed of responding to warning symbols.

An important function of pictorials is to facilitate warning comprehension. Comprehension is the degree to which the recipient understands the warning, based upon the intended meaning the warning is designed to convey. Both the ISO 3641-1 Standard and the ANSI Z535 Standard have established minimum acceptable levels of comprehension by the general population (67% and 85%, respectively). But in China, the relevant standard has not referred to acceptable levels of comprehension. Below (see Fig. 6) are three examples of a warning format recommended in design guidelines in GB2894-2008.

3.2.3 *Placement and layout*

Placement or location relates to where the warning will be embedded within a context of use. Warnings are most effective when they are presented proximate (in time and space) to the hazard (Wogalter and Conzola et al., 2002). The placement of warning signs is not a transparent process, Krisp, J.M. et al. applies a well-documented computational method to identify the wildlife warning sign placement in southern Finland (Krisp and Durot, 2007). Frantz has studied the placement of warning, and using task-analytic approach to generate alternative warning locations (Frantz, 1993; Frantz and Rhoades, 1993; Frantz and Rhoades et al., 2000).

Researchers find that warning layout (spatial structure) and organization (semantic structure) can also influences effectiveness. It can affect the readability and memorability of warning information. Some results may be as references for placement design, such as: warning in outline form is regarded as more appealing, easier to process, and more effective than other layouts.

3.2.4 *Other parameters*

Besides these parameters mentioned above, color, shape, size, auditory warning and receivers' characteristics are also the necessary factors considered in warning design. In practice, color is usually coordinated with shape and light (Easterby and Hakiel, 1980; Hussain and Arens et al., 1991), and the applications of color can facilitate comprehension and perceptions (Kline and Braun et al., 1993; Braun and Mine et al., 1995; McDougald and Wogalter, 2013). Generally speaking, larger size means more salient; another aspect of size is the signal word-text size, the difference of size affects readability of the warning (Silver and Braun, 1993). Auditory warning may be used when the visual environment is unavailable and when the message is relatively short and simple. Visual with auditory warning have been widely applied in transportation and many industrial systems, a proper type of auditory alarm is effective for eliciting perception of hazards (Chan and Ng, 2009).

As for receivers' characteristics, these contain demographic variables such as gender, age, work seniority, cultural and educational background, product or task familiarity and training, and individual differences. The researches on individual issue focus on the Need for Cognition measured

through NFC (Need for Cognition Scale), which is regarded as an important cognition factor influence of hazard perception and further of rules and warnings compliance (Gramann and Bonifield, 1995). More specific of warning's participant, more effective for behavior obeying. It was found that warning containing a direct reference to the individual led to higher compliance compared to a warning containing no reference to the individual (Wogalter and Brelsford, 1994; Wogalter and Young, 1994). These issues will be further discussed below in part of influencing factors.

4 EFFECTIVENESS OF WARNING

Guidelines for warning sign design and measures of the effectiveness should be compatible. In fact, due to ethical constraints and measurement method, very few warning sign have actually been evaluated or tested for efficacy.

4.1 *Evaluation processes and methods*

As referred above in the article, warning sign is a safety (risk) communication, with the intent of evoking the safety behavior (act). To determine whether a warning is effective, a systematic evaluation process (method) is indispensable. Evaluation processes fall into two main categories, formative and summative evaluation, which successively occurs while the warning is being designed, and after all design activities have been completed (Ballantyne and Hughes, 2006).

Formative evaluation means diagnostic use of assessment to provide feedback to participants over the process of design, which supports iterative design of warning sign, so that the warning can be changed repeatedly throughout the process, until a final iteration is agreed upon. As in education field, efforts to strengthen formative evaluation can produce significant learning gains in the test scores of the students (Black and Wiliam, 1998), so does the warning design. It means the ease of identifying problems early in the design cycle, and is a beneficial method.

After all, not all the factors can be identified in the design cycle, so summative evaluation is needed, which is a basis for actual result and for warning improvement. Summative evaluation can be the sole approach to evaluation, or it can be combined with formative evaluation. In summative evaluation, the final product (warning sign) must be "released" into the context of use, and then criterion measures can be gathered from participants over a period of time.

Recognition Test and Recall Test (Cairney and Sless, 1982), sample questionnaire survey (TAY and DE BARROS, 2010), digital questionnaire interview (Vardavas and Connolly et al., 2009), face-to-face interview(Rother, 2005), literature searches and expert selection, hybrid communication/human information processing model analysis, stimulus, laboratory experiments are the evaluation methods employed by researchers.

4.2 *Evaluation criteria and indicators*

To gain evaluation result, criteria and indicators used must be careful selected. In terms of communication theory, measures of noticeability, comprehension, legibility, understandability, recall, reaction time, compliance and search time have been used to assess effectiveness. Besides, subjective ratings of hazardousness, risk, as well as likelihood of injury, likelihood of compliance are often used. In addition, measures of the intermediate processes concerned with the stages of the information-processing model (e.g., attention), which occur prior to behavioral compliance. Other methods to gain subjective report can include paired comparisons of design alternatives followed by ratings of various dimensions such as likelihood of compliance, and these indicators are commonly employed in formative evaluation.

Recall (recall accuracy) is in common use in warnings evaluations as the objective measure indicator. Incidental recall accuracy can reflect the extent to which the warning communicated the risk information and simulated real-world exposure scenarios.

4.3 *Evaluation considerations and influencing factors*

Whether a warning sign is effective depends on many aspects, which can be categorized as internal factors and external factors, from the viewpoint of warning sign. So-called internal factors refer to the warning sign itself. So it is coincidence with design parameters, which means good design is an important element in effectiveness. The specific factors can be discovered above.

The external influencing factors which are commonly employed contain demographic variables, emotion, training and familiarity, situational, safety climate. Demographic variables refer to age, culture/ethnicity, gender, length of service, individual experience, etc.. For example, it is usually a consensus that older individuals have greater difficulty in understanding warning.

Situational factors include many elements, such as familiarity and training, risk perception, rewards and punishment, cost of compliance which is regarded as a critical factor to compliance intent and behavior. Safety climate belongs to organizational element which is made up of

personal communication, administrative situations, and work environment.

5 GENERAL DISCUSSION AND CONCLUSION

During the past 30 years, warning research has made substantial progress in design and effectiveness issues in Europe and America, which can and should be guideline for more effective warnings and for more scientific standards and regulations in China. In terms of the severe reality, there is golden opportunity as well as great challenge for warning research, it answers very well for coal mine.

Warnings sign should be designed to be noticed and encoded and to provide enough information to evoke compliance and safe behavior. The factors that should be considered include two aspects, design parameters of the warning sign, and characteristics of the target user and situation. Design parameters include format factors such as wording, color/contrast, pictorial symbols, size, layout and placement, and content factor that should be expected to matter is explicit information considering hazards, consequences and introduction.

About effectiveness, the evaluation process can be classified informative and summative evaluation which successively occurs while the warning is being designed, and after all design activities have been completed. And the measure methods contain subjective and objective measures, of which subjective measure is more applicability. Different indicators of subjective measures, including behavioral intent, usability, noticeability, guessability, comprehension, reaction time, etc. converge on the same or similar results: behavioral compliance, while recall(such as incidental recall accuracy) and attention are usually the indicators measured in objective assessment. The influencing factors often be used contains demographic variables, emotion, training and familiarity, situational, organizational safety climate.

In conclusion, these parameters and factors above-mentioned should be considered in the future enacting and revise of standards and in the future design of warning sign. And these front researches could and should support a cost-efficient, user-oriented technique to the design of warning sign, and further result in more effective warning system that in turn contribute to product and environmental safety.

Study on special protective clothing of coal mine

Jian Yao & Dongmei Tian
North China Institute of Science and Technology Safety Engineering, Beijing, China
Key Laboratory of Mine Disaster Prevention and Control, Hebei Province, Beijing, China

ABSTRACT: The coal miner's work first of all to ensure the safety and health at work, which is one of the most basic premises, is also a manifestation of social progress. Miners protective excellent performance clothing to protect miners' in the daily work of health, ensure safety in production. Based on the analysis of the underground environment of coal mining and the future trend, describes in detail the specific requirements of coal mine occupation safety of miners protective clothing, so as to meet the requirements of modern coal mine production safety, build a solid and reliable safety for coal mine workers.

1 INTRODUCTION

China is one of the main coal-producing countries in the world, the coal industry production value, profit and contribution to GDP growth in the display industry and future development potential. However, due to coal mining investment in safety facilities and guarantee ability is insufficient, safety consciousness, the coal mine production safety accidents occur frequently. At present, the miners in personal protective equipment including safety helmet, miner's lamp, overalls, gloves, wading boots, self-rescuer, etc (Cheng 2010). Which overalls belong to basic labor insurance supplies, just play a basic role, such as clothing, wear-resisting, resistance to hook for mine risk factors existing in the basic no protective functions, reach the purpose of security miner life safety and body health.

Is the purpose of this paper is discussed in the process of production in coal mine to the specific requirements of the occupational safety and protection for miners and mining protective clothing fabric requirements and the latest design concept and its development prospect, for the safety of the miners.

Modern coal mines work clothes is protective clothing with special function, can adapt to the coal mine complex work environment, to better protect miners' life safety and health. Based on the important role of mining protective clothing in coal mine production, both at home and abroad in the mining design of protective clothing are of different levels of study.

Check related data; we have a standardized research on protective clothing at home and abroad comparison:

First of all, the research on the standardization of protective clothing in China started relatively late, and abroad, especially in western developed countries, industrial revolution earlier, in the process of production workers may face the dangers of understanding more deep, so early in the standardization of protective clothing research development.

Secondly, the imperfect protective clothing standardization system in our country, and the western countries to produce all kinds of protective clothing, protective clothing performance test method standard is also very complete, high standardization degree, has formed a relatively perfect standardization system. EN standards system such as the European Union, the United States ANSI standard system, Japanese JIS standards system, German DIN standard system and the British BSI standards system. The most perfect is the international organization for standardization system of ISO standards.

In addition, our country at present the standardization study of protective clothing has many problems. Protective clothing, for example, the standard system framework is not comprehensive, protective garment production enterprises to participate in the extent of the standards is not enough, all kinds of protective clothing performance testing standards of research funding shortage, for real life safety is related to specific workers in protective clothing is equipped with and using less standard.

Through the above comparison, we can see that with the west in our country at present stage in the standardization of protective clothing research has the very big difference; a lot of research is worth us to draw lessons from abroad. We should intensify efforts to research the suitable protective clothing in coal mine.

2 THE COAL MINE OF PROTECTIVE CLOTHING FABRICS

Coal mines in China are widely distributed, protective clothing for the protection of the coal mine is very important for the safety and health practitioners, the current in coal mine special protective clothing in the process of the management and use, the state-owned key coal mine, local state-owned coal mine and the villages and towns coal mine there are some problems, enterprise to issue some of the protective clothing comfort is poorer, is uncomfortable to wear, or even influence work, cause the employees don't want to use the protective clothing, must cause we attach great importance to these problems.

In order to adapt to the environment underground, mining protective clothing in the fabric design must meet certain requirements. Here first on the market at present the main several requirements of protective clothing fabrics.

2.1 *Functional requirements*

1. Anti-static
   The cause of the underground coal mine gas explosion, one is electric leakage caused sparks gas explosion (Chen et al. 2010). Second is human body electrostatic sparks caused by gas explosion. Spark damage is the most common form of coal mine electric injury. Therefore in coal mine safety in production, we should seriously consider workers clothing, avoid clothing friction caused by static electricity, and reduce the gas explosion accidents.

   Considering the downhole complex natural conditions, humidity is also different, to the miners equipped with anti-static properties of the pure cotton fabric clothing, is the current coal mine production safety have to implement the most basic work.
2. Flame retardant
   Coal mine working environment cause the hidden trouble of the combustion is more, and mean to operate near the melted metal (Gao et al. 2011). In addition, there are many flammable and explosive substances, in a flash fire accident in which has the function of flame retardant protective clothing, can protect the body from damage within a certain amount of time.

   Miners protective clothing usually adopt natural fiber fabric, internationally commonly used natural fiber methods mainly include Proban flame retardant finishing of fabrics and Pyrovatex CP method of two types (Hu & Xing 2008): the former flame retardant, good resistance to wash fabric strength loss is small, but the feel of the treated fabric softness, color change is bigger, but also need special ammonia fumigation equipment; Have little impact on the latter for fabric color, feel is soft, without special equipment, is currently the most rapidly growing finishing methods.
3. Dust proof
   At present our country is still more than most of the coal mining face dust concentration national occupational health standards, a serious threat to the miners' health. Dust is mainly through the respiratory tract and skin penetration into the body, pneumoconiosis disease of coal miners as occupational diseases.

   According to the characteristics of the large underground work dust concentration, should according to the nature of the miners working with from the suction filter type dust respirator, at the same time requires protective clothing work closely with the miners. Openings in the neckline, cuffs, and hem parts for dustproof design, fabric should also have good dustproof performance, in order to ensure the occupational health of the miners.
4. Waterproof and oil-repellent
   Miners in the labor operation will often come into contact with water or the liquid medium such as oil, this kind of medium can clothes, skin contact, cause human body contamination infection or causes rheumatism disease, so the miner's protection should have the function of waterproof and oil-repellent.

   Antistatic, flame retardant and waterproof oil-repellent is contradictory, normally because of anti-static and waterproof oil agent, such as organic silicone, static acid derivatives are combustible materials (Li & Li et al. 2009), they Shared with flame retardant, on the one hand can make the per unit area of fabric with flame retardant agent on the relative reduction; On the other hand, antistatic agent, waterproof and oil agent more attached to the surface of fiber, the fabric on the surface of the combustion increase (Li 2011). Use of organic conductive fiber, phosphate flame retardants and fluoride compound waterproof and oil agent compatible technology can make the fabric fabric with antistatic, flame retardant and waterproof and oil properties (Lian 2009).
5. Warning
   Protective clothing to stain resistant generally large area USES brunet, this stone color approximation with downhole, underground work in the car and are relatively dense, heavy car and driving the driver's vision "blind area", it is easy to happen accident (Miao 2010). So,

in the homework in dangerous environment and protective clothing should be local miners using high luminosity of the material, in the clothing of the chest, back, waist, thigh, knee, setting up reasonable reflective article, in order to play a warning role. In addition, in the process of rescue, high luminosity of the material is easy to identify, to accurately position the miners' life safety to ensure the miners.

2.2 *The technical requirements*

Our country is one of the earliest productions of protective clothing in the world. With time development, the design of the protective clothing differentiation, set all kinds of protective clothing in China national standard, put forward the "safe, applicable, beautiful, generous" (Wang 2009), the general requirements of, for protective clothing design, management, research, and the system elements such as bidding and using make procedural management specification.

Aimed at the particularity of the miners, the state introduced a coal industry standard MT/T 843-843 "the miner's ordinary work clothes" (Wang 2012). This standard is mainly applied to pure cotton fabric, the principles of design, fabric selection, technical requirements, test methods were compared for specific provision, the main protection in the underground work normal damage and dirt. Moreover, GB 12014-2009 "antistatic clothing and GB17956-2000 standard" dusters "and so on is that of has a dustproof and function of anti-static work clothes quality requirements, performance index and test method to make the provisions of the (Wu 2012). Along with our country to the safety of the coal industry are becoming more and more attention, the miners protective clothing required technical requirements also more and more, and our country about the miners' protective clothing standards are not perfect, need to related department to improve as soon as possible.

2.3 *Comfort requirements*

Underground work has its particularity, the labor intensity is big. Under bending, stretching knee, clothing must apply the principle of ergonomics in the design of the structure, the underground work environment of the human—clothing—environment system characteristic (Xie et al. 2011), establish reasonable clothing "environment". As the second skin of human body, underground work should consider more the comfort level of the underground work requirements.

2.4 *Aesthetic requirements*

Research has shown that underground work should not only attach importance to protection, soft protection should also be fully appreciated. Some experts put forward soft protection is to point to by color, style and so on to the operators' psychological protection; and hard protection is to point to by material, design, physiological protection structure for the operators. Underground work clothing color and style design to influence the psychological safety of the miners, it is also one of mine occupational safety factors to consider.

2.5 *Hygiene requirements*

Complicated in the underground work environment, change of temperature and humidity, and downhole operation work and job level have different features, human-computer interaction, miners' protective clothing should meet the demand of different category assignments of hygiene.

According to each part of the human body movement during operation conditions and needs, the miners should be considered the performance of protective clothing fabrics is not unity (Xiong & Chen 2008). Due to large underground work exercise, for example, often under the environment of high temperature operation, under his arm, shoulder and other areas with preferable fabric moisture absorption moisture splicing; In protective clothing of miners neckline appropriate USES cotton knitted fabrics in order to improve the touch with his collar and neck, and in the operation to contain larger body parts with elastic fabric design.

The requirements of the protective clothing fabrics plays an important role in the actual downhole operation, however, is the current research situation in our country, most of protective clothing is still cannot achieve the required level, can maximum limit protect miners' health and safety.

Relevant data show that water is a major cause of underground personnel casualties occur, so, functional ways, from the homework take increase in permeable accident rescue function should bear the brunt. Miners' protective clothing with a life-saving device is in the fabric and material between joining a controlled balloon, the balloon light weight, wear comfortable, in does not affect the normal work at ordinary times (Yang et al. 2010). Man dressed in flooded when the initiative can be inflated, upper body form the airbag cover, effectively prevent the workers suffered from impact damage, and effectively protect the main parts of the body from strong impact and damage.

3 NEW COAL MINE WORKERS OF PROTECTIVE CLOTHING FABRICS DESIGN TRAIN OF THOUGHT

From what has been discussed above, protective clothing fabrics design scheme can have the following kinds.

1. The cotton fabric finishing, antistatic, flame retardant effect and so on in order to achieve (Yang & Qing 2011), but don't last, it concludes that the fabrics of various performance with the increase gradually reduce the number of washing, and pure cotton after finishing, the fabric strength will be greatly reduced, the feel is rough and hard, this is the technology cannot be improved.
2. Inflaming retarding t and electrostatic prevention were used in the fabric (Yu et al. 2010). A layer of cover membrane which has Inflame retarding t and electrostatic prevention formed on the surface of the fabric evenly. This method to a certain extent, improve the durability of the fabric with double proof, intensity is also improved. But the coating aging flame-retardant antistatic performance is poor, feel is also poor.
3. Make conductive fiber filament embedded in pure cotton fabric, flame retardant finishing on fabric (Zhang et al. 2011). This method can obtain good flame-retardant antistatic performance, but the washing resistance is poorer, flame retardant fabric strength is low, shooting style is still thick and hard.
4. According to the requirements of the coal mine with fabric performance analysis, and flame retardant cotton fiber blended yarn, or directly with pure cotton flame retardant fiber yarn, add conductive fiber to the water in the process of weaving filament, thus give essentially the antistatic flame-retardant dual function, and then carries on the simple finishing, finishing here focus on three, since the strength of flame retardant fiber and conductive fiber filament is much bigger than cotton, fabric ultimate strength, abrasion resistance and so on have been improved.

The main points of the four kinds of solutions together require protective clothing is to flame retardant and antistatic, from the aspects of comprehensive consideration, the fourth design ideal, also is we agreed.

Underground in addition, some working noise is very large, and the environment temperature is high, if you can in the fourth kind of design scheme, on the basis of plus noise proof and heat insulation function to design of protective clothing, coupled with dustproof, waterproof and oil-repellent, can design a set of comprehensive protection ability stronger mining protective clothing.

Protective clothing research, according to the present coal mine has fire retardant anti-static performance very bullish on the prospect of development of protective clothing. First of all, the development of textile flame retardant standard currently has the following three aspects: internationalization and standardization, the performance requirements of comprehensive and multiplicity and the standard quantity and type of increase. Secondly, from the development strategy of flame retardant protective clothing, protective obey such fibers, improve performance, reduce costs; Make full use of domestic conditions, development of flame retardant finishing process (Zhang et al. 2011); Strengthening research of fabric structure, can satisfy the protection performance of flame retardant protective clothing and performance, and can well satisfy the comfort; Strengthen cooperation development, to strengthen coordination and cooperation between various departments, to produce one performance good protective clothing. Finally, in terms of environmental protection, the protective clothes is made of fabric environmental protection, harmless to human health of chemical agent, pigment, and control the harmful substances, in order to realize the virtuous cycle of nature and humanity, technology (Zhu 2011), and achieved very good environmental benefits.

4 CONCLUSIONS

Coal enterprises in our country's achievement of continuous case, the coal mine production safety situation is still not optimistic, coal mine safety accidents have occurred. We must develop a strong protective function of protective clothing, to protect the life safety of mine workers. Based on the existing mining coal mine is expounded on the basis of special protective clothing research requires protective clothing fabrics, including dust, anti-static, waterproof and oil proof, flame retardant, such as performance, technical and protective clothing, comfort, aesthetics and occupational health and to the specific requirements of the special protective clothing miners.

According to new research, made protective clothing fabrics and flame retardant fiber, flame retardant and antistatic properties are very good, has the broad prospects for development, the study on people's life and property security, promote the sustained and steady development of the coal industry in China, speed up the process of our socialist modernization construction has the very vital significance. Hope this paper the uniform national standards and industry stand-

ards for miners' modification and redesign play a role in promoting, further to the coal industry in our country to provide a solid guarantee of safety production.

How to improve the psychological quality of mine rescue commanders and fighters

Qi-Zhong Li
North China Institute of Science and Technology, Beijing, China

ABSTRACT: Qualified mine rescue commanders and fighters must have good psychological quality, and good psychological quality of the mine rescue commanders and fighters is a can not be ignored factor for a successful rescue of coal mine accidents. The mine rescue commanders and fighters should strengthen the training of technical and theoretical, at the same time, they should improve psychological quality in usually. The paper discusses an effective way to improve the psychological quality of mine rescue commanders and fighters.

1 INTRODUCTION

A person's psychological quality which based on the innate quality is gradually formed by the influence of acquired environment and education. Psychological quality includes the human ability of cognition, emotion and emotion quality, character, temperament, personality and so on.

Good psychological quality is an important component ability of a rescue commanders and fighters. Mine rescue team is specialized staffs who handle and rescue disaster of mine fire, flood, mine gas and coal dust explosion, gas outburst, etc. In terms of job nature, the rescue commanders and fighters must be facing the bad, dangerous working environment, sometimes endangers their personal safety. So they must have the good psychological quality in the handling of disaster, which directly affect the rescue to be successful or not.

2 UNFAVORABLE FACTORS INFLUENCING THE PSYCHOLOGICAL QUALITY OF THE RESCUE COMMANDERS AND FIGHTERS WHILE THEY ARE WORKING

Some unfavorable factors such as fear, emotion, fluky psychology, psychological dependence and the paralysis of thought often appear in the disaster relief, which influence the psychological quality of the rescue commanders and fighters Because of these factors will lead to adverse psychological state of the rescue commanders and fighters, some mistakes will be making in the rescue process, and it will cause the failure of rescue work.

2.1 *Fear in harsh environment*

Fear is a strong and depressed emotional state which individuals or groups felt deeply in danger of real or imagined. It often manifests as nervous, fear, inability to concentrate, mind going blank, and inability to correctly judge or control behavior. Fear is an innate emotional response of all animal including human. Fear is emotional reaction to an expected to be hurt or unpleasant when face stressors, which usually cause avoidance behavior.

2.2 *The emotional psychology in stress state*

Study on physiological psychology shows that, when face major emergencies, people will produce a stress state. Stress refers to the adaptive responses of people to some unexpected environmental stimuli. When people encounter some unexpected danger or face some unexpected events, people's body and mind are in high tension, this high tension is called the stress state. "Stress" can be simply described as "great confusion of psychology", which will produce the general excitement, cause the scope of attention and perception to be narrowing, cause the speech is not standardized and incoherent, cause behavior disorders. In the mine accident rescue, if mishandled, they will cause their casualties.

2.3 *Fluky psychology caused by empiricism*

Fluky psychology is the illusion of human's cognition and thinking, when they gain success or removed from the disaster by accidental. Some rescue commanders and fighters think that it no problem to do so the past or they often do it by this

way but nothing happens, they clearly know it is illegal operation, but they still insist on doing.

2.4 *Anaclisis and paralysis of the mind*

Anaclisis is a kind of state of mind without resolution or autonomous when people deal with problems. For example, in the treatment of an accident, the new commanders and fighters blindly follow the elder without according to procedures. Paralysis of thought manifest as free riding, and inobservance for the rules of operation.

3 EFFICIENT WAY TO CULTIVATE THE GOOD PSYCHOLOGICAL QUALITY OF RESCUE COMMANDERS AND FIGHTERS

The cultivation of rescue commanders and fighters' psychological quality, is a gradual process of constantly overcoming congenital mental deficiency, constantly honing mind, gradually enhance psychological adaptability and gradually improve the psychology bearing capacity. It will not complete in a short time, and it is not only have relationship with their internal factors such as psychological temperament, character, volitional quality, control ability and so on, but also cannot separate from subjective efforts such as personal learning, experience accumulation and good at summarizing. Therefore, the cultivation of the psychological quality mainly depends on the ability of the self psychological transformation and cognition. Their deficiencies in temperament, character and will can be gradually overcome and consummated through practice.

3.1 *Attaching importance to accumulation of actual combat*

The battlefield is the best training ground. The experience accumulation of rescue commanders and fighters officers are from the mine rescue actual combat, which is an important way to improve the psychological quality. Every rescue operation is a time of baptism and challenge of mind. The so-called unruffled senior general demeanor come from their own knowledge and combat experience. Through the actual combat, they will increase their own knowledge and accumulate experience.

3.2 *Attaching importance to summary of actual combat*

There will have successful experience in every mine accident rescue and must have space to summarize. Be good at summing up experience, taking lessons bravely, it is an important measure to improve their own quality and command ability for all level rescue commanders and fighters. Therefore, they must sum up experience, analyze problems and learn the lesson in order to promote their command ability.

3.3 *Attaching importance to theory and case learning*

The on-the-spot psychological quality of rescue commanders and fighters closely related to their cultural background and professional theoretical level which make their adaptation to the disposal of gusty mine accident will be stronger, psychological quality can be better reflected in the disaster. The theoretical study includes the basic theory of rescue, mine rescue skills and tactics, psychological knowledge and common sense, typical mine rescue case etc. Because they are difficult to experience various types of disasters and accidents, so it is particularly important to strengthen the research and analysis of the case. They should constantly acquire knowledge from heavier, large mine accident rescue case, once encounter similar accident, they will have certain psychological preparation, well-thought-out plan, calm response and scientific disposal method.

3.4 *Attaching importance to random drilling*

Random drilling is an effective way to improve psychological quality and practice ability of organization, which can make the on-the-spot reaction, insight, associative memory and will get testing and training in full. It test the rapid response capability and the ability to adapt changing circumstances of rescue commanders and fighters, and it is a good chance to check out whether a rescue commanders and fighters have good psychological quality and solid comprehensive service quality or not.

3.5 *Attaching importance to psychological adjustment*

Mine rescue teams struggle with the mine disaster for a long time, their members are always in a state of readiness, especially in the mine accident rescue process, they are always in a tense and busy fighting. So tension, fear and other bad state can hardly be avoided, once these psychological problems cannot be solved effectively, the psychological pressure cannot discharge timely, it may lead to psychological illness, lead to excessive tension and fault in decision-making in rescue. In recent years, the psychological adjustment ability of the mine rescue team is incorporated into the routine training. The method includes self mental relaxation, image reproducing, hint, transfer and the

conversation to firm confidence. Some of the rescue team has also opened up a mental health Web site, the psychological consultation room, catharsis room and comprehensive psychological training field, hired or fostered qualified counselors, to further strengthen the psychological health education and psychological counseling for the members. They focus on improving the self-control ability, the self-adjustment ability to ease the pressure, enhance the adaptability, improve the comprehensive psychological quality and command level.

3.6 *Fostering stable emotional state*

In the intense process of rapid transformation of rescue success and failure, the emotion of rescue commanders and fighters will have some drastic changes which will have positive or negative influence on action effect of the rescue team and their ability of body. A high degree of political awareness, responsibility and sense of honor is the important aspect of fostering emotional stability. Therefore, they should pay more attention to it in peacetime.

4 CONCLUSION

Mine rescue is a very sacred, very dangerous and very hard work. Their mission is walk along the reverse route of escape direction. Whether mine rescue is successful or not is determined by the interaction of inside conditions which is formed by the combination of the body, technology, tactics, psychology, conducting art, missions and other factors. But the psychological factor is one of the most important factors. Many failed rescue case shows that bad psychological quality is an important cause of its casualties and failure of rescue. It can be said that bad psychological factors are significant potential safety hazard of mine rescue. Therefore, we must pay special attention to improve the psychological quality of rescue commanders and fighters.

Assessment of Emergency Preparedness Effects of work safety in Xinjiang autonomous region of China based on weighted Rank Sum Ratio

Wenxun Zhang & Fanqi Kong
Xinjiang Academy of Safety Science and Technology, Urumqi, China

Tianhan Jiang
China Academy of Safety Science and Technology, Beijing, China

ABSTRACT: Emergency readiness assessment of work safety in Xinjiang autonomous region, China, is carried out to provide evidence for constructing Xinjiang's work safety emergency ability. Four work safety indicators are selected as assessment indices. The weighted Rank Sum Ratio (RSR) method is used to assessment the effects of work safety emergency management of 15 areas in Xinjiang. The results show that the emergency preparedness of work safety in the above areas is generally fine. And the work safe risk in Xinjiang has declined in the past years.

1 INTRODUCTION

There are many factors such as safety strategy, control target for work safety, safety regulation, safety management structure, etc., affecting regional work safety risk. And it is difficult to evaluate the control level of regional work safety risk. Emergency preparedness is known as the disaster preparedness, used to be a part of the four stages of emergency management "reduction, preparedness, response, recovery" (Sutton J & Tierney K 2006). It is defined as "The cycle of United States emergency preparation includes planning, organization, equipment and training, assessment and improvement of key link, to be enhanced the whole process of action "prevention, protection, response, recovery" (U.S. Department o f Home land Security 2009). Recently, Jiang & Deng (Tianhan Jiang & Yunfeng Deng 2012) presented a novel assessment method of regional Emergency Preparedness Effect (EPE). Quantitative indices of fatalities and economic loss are selected from natural disasters, accidents, social events, and public health events. The results showed that the EPE in China is getting better, while the overall levels of emergency inherent risk have dropped down in recent years. The assessment framework of regional emergency preparedness is effective, and the method is feasible. In this paper, we improved the above method to assessment the effects of work safety emergency management of 15 areas in Xinjiang autonomous region, China.

2 METHOD

2.1 *Assessment index*

A comprehensive national control indicators of relative index are selected as the basis of risk indicators in this paper (Xianzheng Wang 2004). Different weights are assigned to those indices, including Mortality of one Hundred Million Yuan (MHMY, 30%), Mortality of one Hundred Thousand Workers (MHTW, 40%), Mortality of Ten Thousand Vehicles (MTTV, 25%) and Mortality of Million Tons in Coal Mine (MMTCM, 5%). MHTW is most important, which can reflect the risk level of mining and trading industry. The second is MHMY, and the third is MTTV. Considering the Xinjiang coal mine accidents are severe, relatively large impact on mortality, MMTCM is included in this paper.

2.2 *Assessment method*

The weighted Rank Sum Ratio (RSR) method (Shaojiang Yang 1994) is used to assessment the work safety risk of 15 areas in Xinjiang as follows.

$$PSRI_j = \frac{\sum_{J=1}^{K} R_{ij} W_j}{N \times \sum_{J=1}^{K} W_j} \tag{1}$$

where, $PSRI_j$ (j = 1, 2,...,N) is the rank sum ratio of the ith City. N is the total number of cities to be

assessmented. R_{ij} is the rank of the jth index in the ith city. W is the weight coefficient of each index, here, $W_1 = 30$, $W_2 = 40$, $W_3 = 25$, $W_4 = 5$. Results are shown in Table 1.

Then Emergency Preparation Effect Risk Index (EPERI) of local work safety can be calculated according to the literature (Tianhan Jiang & Yunfeng Deng 2012).

$$EPERI = \frac{PSRI_i - \overline{PSRI_{i-1}}}{\overline{PSRI_{i-1}}} \times 100\% \quad (2)$$

3 RESULTS

The data from 2007 to 2011 used in this paper of work safety risk were obtained from Xinjiang work safety supervision and Management Bureau dispatch statistical information center (4 relative indices). The results were shown in Figure 1.

Figure 1 shows the work safety risk changes in different regions of Xinjiang from 2007 to 2011. Overall, the safety risk is roughly identically distributed in each year. High risk value may be followed by high risk value in next years. These results showed that the risk level of work safety can reflect the inherent risks of work safety of a city. And Kezhou's work safety risk is significantly higher than average risk of work safety in Xinjiang, China.

EPERI from 2007 to 2011 of 15 areas of Xinjiang is also calculated. The results are shown in Table 1 and Figure 2.

As is shown in Figure 2, Xinjiang work safety risk level is declining from 2007 to 2011, which reflects the work safety emergency preparedness effect gradually improve. The emergency preparedness effect was poor in Tacheng; The safety risk level didn't change in Hetian, and its emergency preparation effect was not obvious. The remaining 13 areas decreased, especially Hami, Kashi, and Changji Zhou was obvious, and emergency preparedness were better.

The work safety risks changed in Xinjiang from 2007 to 2011 are shown in Figure 3. From Figure 3, MMTCM, MTTV and MHMY decreased year by year, MHTW showed a downward trend, in addition to rebound in 2010. By comparing the results in Figure 2 and Figure 3, the declining trend is same. It indicates that the overall work safety risk decrease, and the emergency preparedness effects are fine in Xinjiang, China.

Bazhou, Hotan, and Tacheng is selected for analyzing the emergency preparation effect of work safety, among which, Bazhou can represent the regions with better emergency preparation effects.

Table 1. The work safety risk index and emergency preparedness effects in Xinjiang, China.

	2007	2008	2009	2010	2011	EPERI
Urumqi city	0.32	0.4	0.3	0.32	0.21	–18.87%
Changji zhou	0.86	0.52	0.44	0.24	0.32	–33.98%
Bazhou	0.59	0.45	0.44	0.27	0.28	–24.72%
Kashi	0.79	0.46	0.3	0.21	0.23	–41.55%
Yilizhou	0.41	0.36	0.28	0.22	0.27	–19.93%
Turpan	0.57	0.66	0.55	0.39	0.39	–21.44%
Hami	0.58	0.42	0.36	0.51	0.4	–41.89%
Bozhou	0.48	0.28	0.26	0.24	0.16	–26.93%
Aksu	0.61	0.83	0.57	0.61	0.45	–18.90%
Kezhou	2.16	3.6	0.73	1.24	0.31	–62.11%
Hetan	0.2	0.11	0.26	0.16	0.13	0.19%
Tacheng	0.41	0.28	0.32	0.56	0.3	9.07%
Altany	0.21	0.22	0.15	0.17	0.12	–22.13%
Karmay city	0.16	0.18	0.19	0.15	0.16	–5.02%
Shihezi city	0.19	0.17	0.14	0.17	0.12	–11.13%

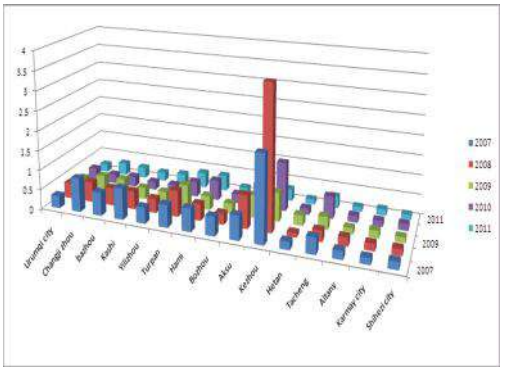

Figure 1. Changes of work safety risk in Xinjiang regions from 2007 to 2011.

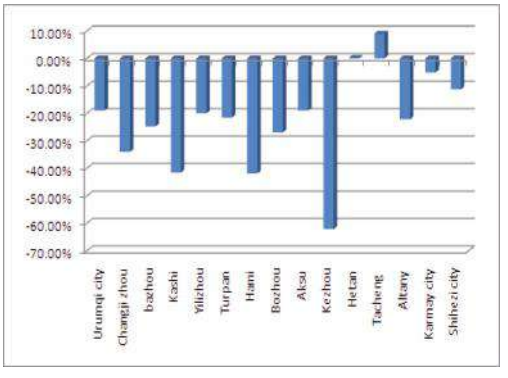

Figure 2. Emergency preparedness effect risk index of Work safety in Xinjiang regions.

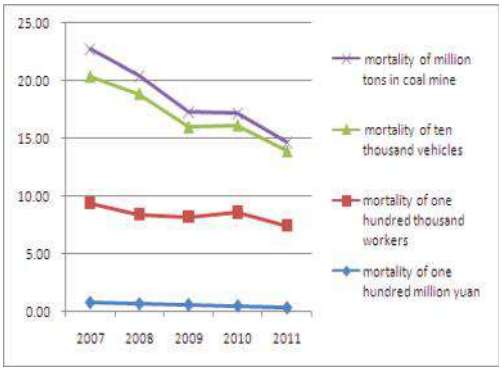

Figure 3. Xinjiang safety production 4 single safety risk (safety relative index) annual variation.

Hotan represents the regions with the general emergency preparedness effects. Tacheng area is less effective in work safety emergency management.

MHMY and MTTV in Bazhou decreased year by year; MHTW and MMTCM from 2008 to 2011. Overall, the work safety risk in Bazhou decreases, and emergency preparedness effects are fine.

MHTW and MMTCM in Hetian changed from high to low, and from low to high again; MHMY and MTTV has declined, but it was not obvious.

MMTCM and MHTW in Tacheng changed from high to low, and from low to high again; MHMY and MTTV has declined, but the decline is not obvious. Overall, the work safety risk is high in Tacheng, and emergency preparedness effect is poor.

4 CONCLUSION

The emergency preparedness of work safety in Xinjiang is generally fine. And the work safe risk in Xinjiang has declined in the past years, except Tacheng and Hotan.

ACKNOWLEDGEMENTS

We would like to thank the Xinjiang Administration of Work Safety for the survey data provision.

Application of reverse circulation DTH hammer in mine rescue drilling

Fanqi Kong & Xiaolin Lai
Xinjiang Academy of Safety Science and Technology, Urumqi, Xinjiang, China

ABSTRACT: When accidents such as water permeation, mine fire, roof fall occurred under the coal mines, it was important to get through the blocked layer and rescue the persons rapidly, which could reduce accident casualties and economic loss. Conventional DTH hammer drilling technology was often used in mine rescue drilling, and there were many successful examples. Because of many difficulties such as broken formation, rich fractures, and complex downhole condition, such technology brought out many problems such as low speed, low efficiency, and more accidents. In order to solve the problems, this paper introduced the reverse circulation DTH hammer drilling technology, which had outstanding advantages in complex formation drilling such as fast drilling speed, low air requirement, and not being affected by the formation condition etc. The applicability of reverse circulation DTH hammer drilling technology used in mine rescue drilling was also discussed.

1 THE IMPORTANCE OF MINE RESCUE DRILLING

Data from State Administration of Work Safety of China showed that 779 accidents occurred in coal mines across the country in 2012, and caused 1,384 people's death and amazing property losses. According to incomplete statistics, people killed directly by explosion, collapse, shock and other injuries in coal mine accidents only accounted for 10 percent of the total casualties, while 90 percent of them died due to oxygen depletion, toxic and harmful gases with high concentrations, escape routes which couldn't lead to a safe area (Xinda Zhao et al. 2012).

Once the escape routes were blocked, we used to dig through the routes directly or dig a new route for rescue. Such a method usually suffered many unexpected factors, and was difficult to rescue the trapped people before they died (Yuanming Song et al. 2004). For example, 'Qiyi' coal mine in Lianyuan city of Hunan province happened water inrushing in 2003, the exits were blocked by water and mudstones, seventeen miners were trapped in the downhole. Rescue was immediately organized by digging through directly and around the route, six days later, the route got through by digging a new hole, and found that the trapped men died of suffocation.

If we can get through the blocked layer quickly, provide the trapped men air, water, milk and foods to make sure that they can live in the downhole. We can also build up communication with them to calm down their stress feelings, tell them that they were safe and could be rescued. Then, we could dig through the blocked layer to bring them out, as shown in Fig. 1. Such a method could greatly reduce the person casualties and economic losses.

This method was proved effective and feasible by some successful rescues. One of them was the rescue of Chile copper mine in San Jose, collapse happened in the hole of 510 meters from the earth in 2010, 33 miners were trapped. After the accident happened, three holes were drilled to fix the miners' position and supply them water, foods and some other necessities. Sixty-nine days later, the trapped men were rescued by a broadened hole drilled into the earth. The successful rescue

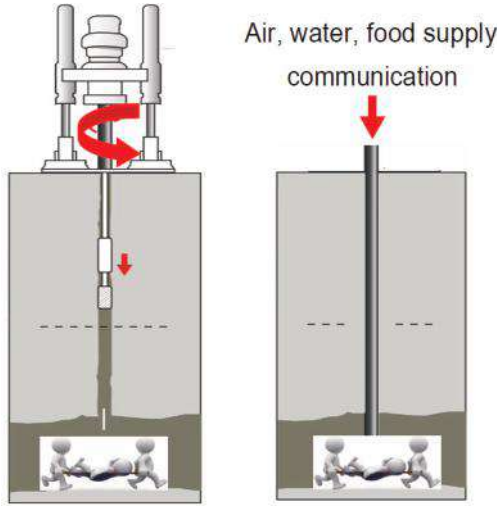

Figure 1. Mine rescue drilling and air, water, food supply.

of Chile copper mine brought great inspiration to the leader of National Workplace Emergency Management Center of China, Zhijian Wang, the executive deputy director, said that we should pay more attention to the study of mine rescue drilling technologies (Zhijian Wang 2011).

2 APPLICATION OF REVERSE CIRCULATION DTH HAMMER IN MINE RESCUE DRILLING

Conventional DTH (drill-the-hold) hammer drilling technology (Fig. 2) often used in mine rescue drilling, and there were many successful examples, such as Chile copper rescue previously mentioned, but there were also many difficulties such as broken formation, rich fractures, and downhole condition complex, using conventional DTH hammer drilling technology had many problems such as low speed, low efficiency, and more accidents. For example, Luotuo Shan coal mine in China happened water permeation accident in 2010, the No. 3 rescue drilling deflected for the complex formation condition, had to reselect the drilling point, and wasted the precious rescue time.

In order to solve this problem, I am glad to introduce the reverse circulation DTH hammer drilling technology (Fig. 2), which had outstanding advantages in complex formation drilling. It had fast drilling speed, low air requirement, and not be affected by the formation condition etc.

2.1 *What is reverse circulation DTH hammer drilling technology?*

The reverse circulation DTH hammer drilling technique is an important constituent part of the Multi-Tech air drilling technology, and more importantly, it is a major breakthrough of air drilling technology. It is combined with DTH impacting breaking rock, flushing medium reverse circulation and continuous coring three advanced drilling techniques into one system, and naturally it has become an integrated high-tech drilling techniques. The hollow-through DTH, reverse circulation bit, and dual-wall drill pipe are constituted the center channel, then the flushing medium along with the center channel forms the reverse circulation, and so the core transportation in the process of drilling is realized and it effectively solved the problem of the orifice dust pollution. At present, this drilling technology is developing rapidly as the application filed which is gradually expanded, and it has got good applications in drilling engineering filed such as geological core exploration, water well drilling and foundation engineering (Kun Yin 1996, Liexiang Han 2008).

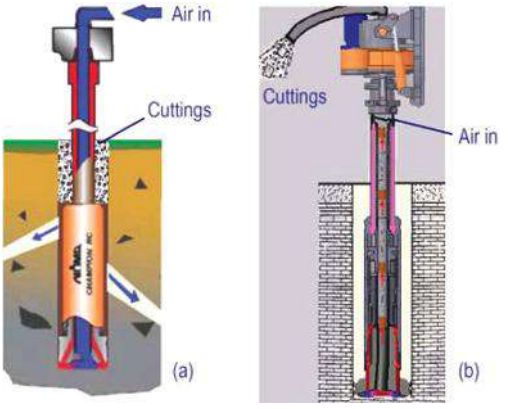

Figure 2. (a) conventional DTH hammer drilling; (b) reverse circulation DTH hammer drilling.

2.2 *What is the difference?*

The essential difference between reverse circulation DTH hammer drilling and conventional DTH hammer drilling is the air circulation mechanism, as shown in Fig. 3.

The compressed air of conventional DTH hammer drilling gets into the drilling system from the centre of drill pipe, transports cuttings from the bottomhole between the hammer casing and the hole wall to the collector sub. The circulation is built on the drilling system and the hole wall. When it encounters broken or rich fractures formation, the air is leak into the formation, and the circulation is hard to build up. While during the reverse circulation DTH hammer drilling, the compressed air gets into the drilling system from the interlayer of dual-wall drill pipe, transports cuttings from the bottomhole in the center of the dual-wall drill pipe to the collector sub. As shown in Fig. 3. Its circulation is built up in the drilling system only, which will not be or less affected by the formation condition. As the cross-sectional area of the pipe center is much smaller than the cross-sectional area of the annulus, with the condition of same amount air supply, the air flow transport with cuttings in reverse circulation DTH hammer drilling is much faster than the air flow in conventional DTH hammer drilling, and so the effect of transporting cuttings is much better, without the repeat break of cuttings, and the drilling speed could be substantially increased (Kun Bo, 2011).

The advantage of reverse circulation DTH hammer could be summarized as follows:

1. Need only one fifth of air supply of conventional DTH hammer drilling.
2. Good in transporting cuttings.

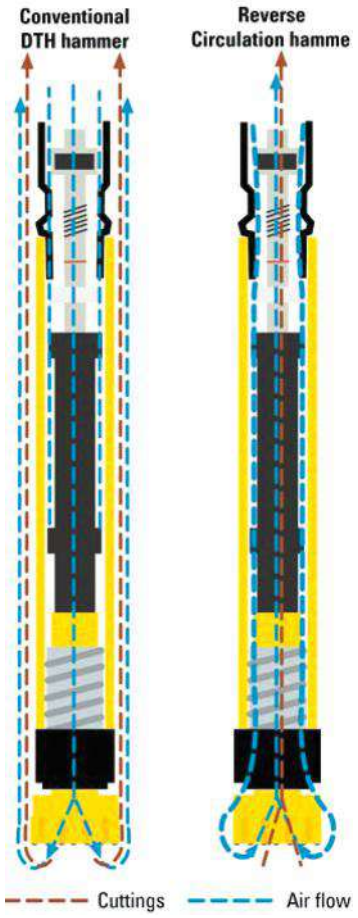

Figure 3. Air circulation of conventional DTH hammer drilling & reverse circulation DTH hammer drilling.

3. Drilling speed is 3–4 times of conventional drilling.
4. Few affection to the hole wall, and less be affected by the formation condition (William C. 2009).
5. Could be used in broken and rich fracture formation without leakage.

2.3 *Applicability in mine rescue drilling*

Before we discuss the applicability of reverse circulation DTH hammer in mine rescue drilling, we should know what is the feature of mine rescue drilling; and what difficulties we would encounter. The features and difficulties of mine rescue drilling are summered as follows:

1. First, the position of trapped miners should be exactly fixed, and then the drilling point be fixed.
2. Drilling speed should be really fast to make sure that the isolated area could be drilled through timely.
3. Maybe encounter broken formation, fracture rich formation, mined-out regions, the drilling mud or air would get lost into the formation.
4. The drilling hole should be big enough to transport air, water, food, and build up communication between the trapped miners and outside people. The drilled hole could be expanded by drilling once again to a larger diameter to get out the miners through the hole.

The reverse circulation DTH hammer drilling technology has lots of advantages as previously mentioned, for example the drilling speed is fast, less be affected by the formation geography, the drill bit diameter range could be 100–200 mm or even bigger, which could meet the requirements of mine rescue drilling.

ACKNOWLEDGEMENTS

The authors would like to thank Dr. Pinlu Cao for his help in preparing the draft, and thank to the financial support of Xinjiang Science and Technology Agency in China.

Study on chemical oxygen source in underground emergency refuge system

Shu Wang, Longzhe Jin, Shuci Liu & Zheng Zhang
Civil and Environment Engineering School, University of Science and Technology Beijing, Beijing, China

ABSTRACT: A series tests were carried out to test chemical oxygen, including chlorate Oxygen Candle (OC) and potassium superoxide Oxygen Regeneration Plate (ORP), with respect to the Oxygen Generation Rate (OGR), surface temperature, toxic/harmful gas production, noise level, and monitor the influence on internal environmental parameters of a sealed mine refuge space, analyze and discuss characteristics of both chemical oxygen sources and things to be paid attention in application. Then it is proposed that chemical oxygen can be effectively used as emergency oxygen source in underground emergency refuge space, especially for high temperature and deep non-coal mines. In this way, additional heat from long-time use of chemical oxygen can be avoided. Meanwhile the safety and reliability of the oxygen supply system can be further increased, and the duration of life-support capabilities in emergency refuge facilities are improved.

1 INTRODUCTION

In underground mining in china, the oxygen supply system is conventionally dependent on a forced air, with compressed oxygen for underground emergency refuge system (Gao et al. 2012). The forced air supply has to be connected with aboveground boreholes through pipelines, thus having poor independence, as it will not be able to supply oxygen once the pipelines are destroyed in mine accidents. The compressed oxygen cylinders need regular maintenance and are prone to quick discharge or explosion due to increased internal pressure if long exposed to high-temperature or fire.

Chemical oxygen, a solid source to provide oxygen by decomposing rich oxides (Qin & Zhang 2009), is typically divided into two categories: one is called chlorate "Oxygen Candle" (OC), made generally by molding or casting mixture of the base metal chlorate, a certain amount of catalyst, chlorine inhibitor, fuel, and binder (Shafirovich et al. 2002, Shafirovich et al. 2003); the other one is the peroxides or superoxides of alkali metals, such as potassium/sodium superoxide and calcium peroxide (Wang et al. 2010). Chemical oxygen has the advantages of being highly independent, providing higher oxygen storage in small volume than conventional underground oxygen supply methods do. Thus it is possible for chemical oxygen generator to be used as oxygen source in underground emergency refuge facilities (including refuge stations and refuge chambers).

However, the underground emergency refuge facilities impose very stringent requirement on its internal survival environment. Therefore, considering the fact that chemical oxygen may have some potential hazards or other problems, for instance, producing toxic/harmful gases or having influence on thermal environment, a series tests on the chlorate Oxygen Candle (OC) and potassium superoxide Oxygen Regeneration Plate (ORP) were carried out to determine their Oxygen Generation Rate (OGR), the surface temperature, toxic/harmful gas production, noise level; the influence on environmental parameters in a sealed refuge chamber was also monitored; then characteristics of both chemical oxygen sources and things to be paid attention in application were analyzed and discussed. This study provides important information to expand the application of chemical oxygen in the non-coal-mine emergency refuge space.

2 EXPERIMENTAL

2.1 *Test platform used in the experiment*

The test platform was comprised of a refuge chamber (Figure 1) with an internal net volume of 6.84 m^3, an air purifier (24V, 30 W) as shown in Figure 2, and a KJ70 coal-mine safe-production monitoring system, which is used to monitor concentrations of such environmental parameters as O_2, CO, CO_2, CH_4, H_2S, temperature, and relative humidity inside in real time.

Figure 1. Refuge chamber.

Figure 2. Air purifier.

Figure 3. Oxygen Candle (OC).

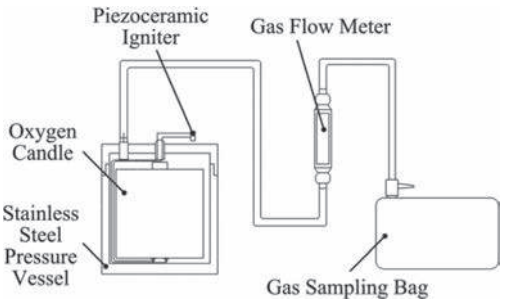

Figure 4. The OC oxygen-producing performance test process.

Figure 5. Potassium superoxide Oxygen Regeneration Plate (ORP).

2.2 *OC oxygen supply performance test*

The tested OC, as shown in Figure 3, was 150 mm in diameter, 180 mm in height, 2.8 Kg in gross weight, produced approximately 300 L oxygen theoretically, and was started with a piezoceramic igniter.

2.2.1 *OC performance test*

1 Oxygen generation characteristics

Here the Oxygen Generation Rate (OGR), oxygen generation capacity, and oxygen purity were monitored. As shown in Figure 4, the OC was placed into a sealed stainless steel pressure vessel, with a piezoceramic igniter and gas pipes connected on the top; the sealed stainless steel pressure vessel was connected with a gas flow meter and a gas sampling bag through pipelines. The OGR of OC was recorded every 30s. And a gas chromatograph-mass spectrograph (Trace DSQ and Trace GC2000) was applied to analyze sample composition.

2 Surface temperature and the Noise Pressure Level (NPL)

The surface temperature was monitored by Pt100 temperature sensors, which were fixed respectively at the bottom, the side wall, the top, and the gas outlet of OC. The Noise Pressure Level (NPL) was monitored by noise analyzer (AWA6270+).

2.2.2 *OC oxygen supply performance test*

The oxygen supply simulation test was carried out to monitor OC's effect on internal environment of the simulated chamber. Five environmental parameters (oxygen content, carbon dioxide content, carbon monoxide content, temperature, and relative humidity) inside the sealed refuge chamber were monitored during one OC's combustion.

2.3 *ORP oxygen supply performance test*

The tested ORP (Figure 5) was composed of 95% KO_2 and 5% asbestos, had an oxygen generation capacity of 203 L/Kg, and CO_2 absorbing capacity of 152 L/Kg. A single plate was 315 mm long, 220 mm wide, 6 mm thick, and 390 g in weight.

2.3.1 *ORP performance test*

In the test, 2 pieces of ORPs were fixed vertically on the reagent bed of the air purifier; keep the purifier running during the test to make surrounding air circulate through ORP at the speed of 5 m/s; CO_2 was forced into the chamber through a pipe at the rate of 1.6 L/min (equal to the CO_2 amount produced by 4 people (Li et al. 2010)). The whole test duration was 90 min, and the environmental changes inside the chamber were obtained

with KJ70 coal-mine safe-production monitoring system.

2.3.2 *ORP-soda lime combined oxygen supply performance test*

The soda lime used in the test has an actual CO_2 absorbing capacity of 97 L/Kg. During testing, soda lime (1.5 kg) was evenly distributed over the bottom of the reagent bed and then ORP was placed vertically. Other test conditions were the same as mentioned in 2.3.1.

3 RESULTS AND ANALYSIS

3.1 *OC oxygen supply performance test*

3.1.1 *OC performance test*

The OGR curve of OC is shown in Figure 6. The OC completed the combustion process within 15 min. The OGR was undulating, with the rate peaks appearing at 0.5 min, 5.5 min, 7.5 min and 10 min, and the rate at 10 min is the maximal, 41.67 L/min. The OC produced a total of 241 L oxygen, mean OGR was 15.38 L/min, and OC's utilization rate was 80.33%.

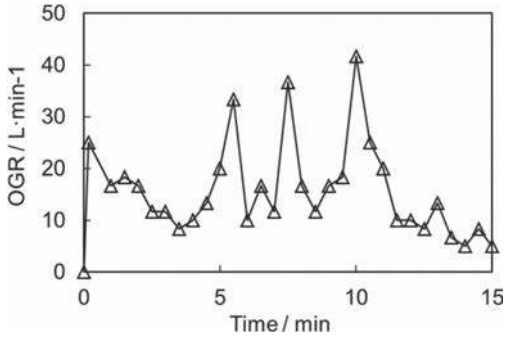

Figure 6. The changing curve of oxygen flow rate.

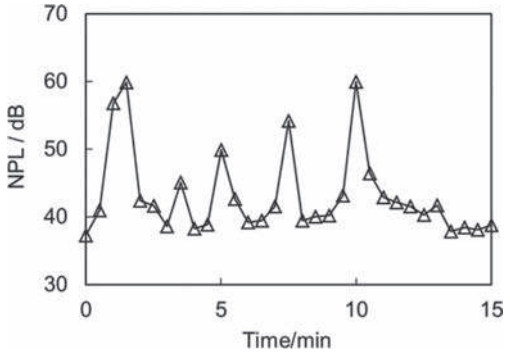

Figure 7. The changing curve of noise value.

Data about noise monitoring during OC burning is shown in Figure 7. At the very beginning, NPL reach the maximum value (59.9 dB) due to intensive reaction of the ignition charge; overall NPL from reaction of the core was lower but increased gradually with ongoing reaction, because continually accumulated heat inside the unit made the decomposition of sodium chlorate more violent.

The observed phenomena indicate that, insulation material of OC cannot be selected based on thermal insulation only. Though good insulation coefficient may contribute to lowering temperature of OC surface, heat accumulated inside the unit may cause OC core's temperature to rise higher, leading to more violent decomposition reaction, increased undulation of the OGR, bigger noise, and also directing the decomposing reaction of potassium chlorate towards producing more chlorine (Sun 1997), increasing possibility to generate toxic/harmful gases such as Cl_2 and CO.

The gas composition of the samples, which were taken respectively during 0~5 min and 5~10 min, is shown in Table 1.

It is observed from the result that, CO was generated mostly at the initial stage due to the incomplete combustion of the ignition charge, for the 1st gas sample contained a little more CO than the 2nd sample do; chlorine was not detected, with oxygen purity up to 97.06% and that was 233.91 L available oxygen. Assuming oxygen consumption rate is 0.5 mL/min per head, the tested OC can produce oxygen for 2 h consumption by 4 persons.

The temperature—time curves at the gas outlet, the bottom, the side wall and the top of OC are shown in Fig. 8. After being started, the OC core

Table 1. The gas composition of samples.

Number	O_2 (%)	Cl_2 (%)	CO (ppm)
1	96.32	0	6
2	97.81	0	2

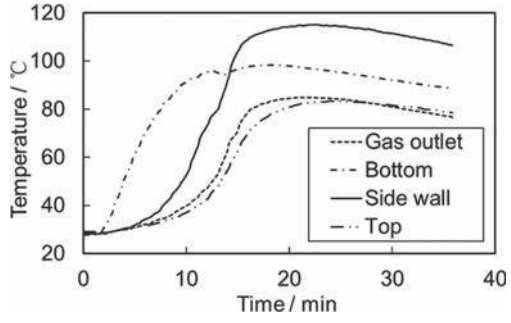

Figure 8. The changing curve of temperature.

was reacting from bottom to top, as a result the temperature at the bottom rose fast, at the rate of about 10°C/min; 10 min later, the temperature of the whole unit rose sharply, and quickly reached the top, which were 115.1 °C at the side wall, 98.3 °C at the bottom, 85.0 °C at the gas outlet, and 83.5 °C at the top; 20 min after OC reaction stopped, the surface was still at relatively higher temperature as the massive heat accumulated inside the insulation was released slowly. In general, the surface temperature met the requirements in national standard Electric Devices in Explosive Gas Atmosphere (GB 3836.1–2000).

3.1.2 *OC oxygen supply performance test*

The values of environmental parameters inside the chamber before and after the test are shown in Table 2. After the test, the oxygen concentration rose from 21% to 24%, slightly higher than the standard level, but this would not happen if there were refugees inside the chamber consuming oxygen constantly; trace amount of CO_2 was generated, negligible; CO was mainly produced at the initial stage of combustion, much lower than the safe limit of 24 ppm; the inside temperature rose by 0.63 °C and RH by 7%, all within acceptable ranges.

3.2 *ORP oxygen supply performance test*

3.2.1 *ORP performance test*

Table 3 shows the changes of environmental parameters inside the chamber before and after the test when using ORPs alone. Theoretically, two pieces of ORPs (weighing 780 g in total) can produce 158.34 L oxygen, which could be consumed by 4 persons for 80 min (assuming average oxygen consumption at 0.5 L/min per head). However the test results showed that, after 90 min, the O_2 concentration inside the chamber rose merely by 0.3%, i.e. 20.52 L oxygen produced at the average OGR of 0.23 L/min; and the average CO_2 absorbing rate was 0.31 L/min; the temperature inside the chamber rose slightly while RH reduced to 31%.

In general, when using ORP alone, both OGR and CO_2 absorbing rate can hardly meet the refugees' respiratory demands, and this mainly resulted from two reasons:

1. The KO_2 on the plate surface reacted with water to generate KOH which then reacted with CO_2 to generate pasty K_2CO_3 and $KHCO_3$, and these pasty substances accumulated gradually on the surface to impede further reaction of steam and CO_2 with KO_2 covered, leading to incomplete reaction of ORP and thus lowering reaction efficiency;
2. Water needed for ORP reaction, which could only come from moisture in air in the test, was limited in the sealed chamber, leading to the low OGR. In the actual usage, massive moisture from refugees may help to increase the OGR to some extent, though the effect not so significant.

3.2.2 *ORP-soda lime combined oxygen supply performance test*

The changes of the environmental parameters before and after the test were presented in Table 4.

After 90 min actions of ORPs (2 pieces) with soda lime (1.5 kg), the O_2 concentration inside the chamber rose to 22.1%, the average OGR increased to 1.14 L/min, which indicating that addition of soda lime contributed to increasing ORP's reaction efficiency, because water and heat generated by soda lime provided favorable conditions for ORP's reaction; with soda lime, CO_2 concentration inside the chamber was under control, and the average CO_2 absorbing rate rose to 2.01 L/min; meanwhile,

Table 2. Changes of internal environmental parameters during oxygen supply performance test of oxygen candle.

	O_2 (%)	CO_2 (%)	CO (ppm)	Temperature (°C)	Relative Humidity (%)
Before	21.00	0.05	1.00	31.88	23.00
After	24.00	0.11	4.00	32.50	30.00

Table 3. Changes of internal environmental parameters during oxygen regeneration plate performance test.

	O_2 (%)	CO_2 (%)	Temperature (°C)	Relative Humidity (%)
Before	20.7	0.03	22.2	45
After	21	1.73	22.8	31

Table 4. Changes of internal environmental parameters during oxygen regeneration plate-soda lime combined oxygen supply performance test.

ORP pieces		O_2 (%)	CO_2 (%)	Temperature (°C)	Relative Humidity (%)
2	Before	20.6	0.07	22.4	62
	After	22.1	0.61	24.1	87
4	Before	20.6	0.04	25.0	60
	After	23.2	0.60	28.5	91

both the temperature and RH rose considerably, but not to the extent endangering human health.

In the case of four ORPs and 1.5 kg soda lime used, 177.84 L oxygen was produced within 90 min, at the average OGR of 1.98 L/min, sufficient for 4 persons' oxygen demand. As the increased quantity of ORPs created a considerable press drop of air passing through reagent bed, which reduced the efficiency of air purifier, thus it was not a simple linear relation between the average OGR and the quantity of ORPs. Additionally, with joint action of ORPs and soda lime, the temperature and RH inside the chamber rose faster, respectively at 28.5°C and 91% RH after the test. In such a hot and humid environment refugees may feel discomforted, even suffering heatstroke, so measures to reduce temperature and humidity have to be taken.

3.3 *Comparison of application characteristics of OC and ORP*

Based on previously tested results, it is concluded that the two chemical oxygen sources, chlorate OC and potassium superoxide ORP have different characteristics in OGR, starting method and reaction conditions et al.

1. Oxygen generation rate

OC produces O_2 quickly (241 L oxygen within 15 min in the test), reacts completely, and the action process is not affected by any external environmental conditions.

ORP is not easy to react completely due to the pasty reaction products accumulated on the surface; its OGR is heavily influenced by external temperature, humidity, air flow speed. When using ORP alone, it can hardly meet the respiratory requirement of underground emergency refuge space due to its relatively low OGR and CO_2 absorbing rate; when used with soda lime, the OGR of each ORP (390 g) rose to 0.5 L/min, meeting O_2 demand of one person.

2. Starting method

For OC, the ignition charge has to be ignited with a mechanical firing pin or an electronic igniter before starting reaction of the OC column, and the reaction, once started, cannot be interrupted. Except the case of too low humidity of the air flow, ORP can start reaction whenever exposed to air, with the reacting rate affected by external environmental conditions.

3. Heat production

Though OC and ORP both release massive heat during usage, there are slight differences between them. As the quick reaction of OC, heat accumulated inside the housing insulation can be isolated from the refuge space if properly treated.

ORP needs to be exposed to air, thus the heat is released to the surrounding environment throughout the whole reaction. In the case of long-time use, the accumulative effect of heat cannot be overlooked because this will necessitate a temperature and humidity control system of higher quality.

4. Safety

Due to the quite intense reaction, OC's surface temperature is relatively high (the measured max. is 115.1°C). Though meeting the requirement in the national standard, necessary safety measures have to be taken to avoid scalding injury.

The trace CO produced by OC is much lower than the safety limit, and can be eliminated by the air purifier in practical application; while ORP would emit trace alkaline dust which would pollute air inside the refuge space with no measure to take.

In addition, OC have no changes for its shape after reaction, and is relatively easy to be treated. In contrast, the products from ORP reaction are possibly pasty due to fusion problem. Furthermore, the ORP that is not reacted completely will, whenever in contact with water, generate KOH, a strong alkali, which is caustic. Therefore, the products from ORP reaction have to avoid contact with water or other organics, making it harder to treat.

4 CONCLUSIONS

In the present study, we evaluated the oxygen supply performance of both chlorate OC and potassium superoxide ORP, and their influence on the internal environment of a sealed refuge chamber. The differences between these two chemical oxygen sources and things to be paid attention in application were also discussed.

OC, once started, reacts quickly and completely, not affected by any external environmental conditions. After reaction in the sealed refuge chamber, the changes of environmental parameters are within acceptable range. Attentions shall be paid to in use of chlorate OC is as follows: firstly, to avoid O_2 concentration exceeding the standard, OC size is to be selected depending on the number of refugees and the volume of the refuge space; secondly, necessary safety measures shall be taken to avoid scalding injury during usage.

ORP is not easy to react completely due to the pasty reaction products accumulated on the surface; its OGR is heavily influenced by external temperature, humidity, air flow speed. When using alone, it can hardly meet the respiratory requirement of refugees due to its relatively low OGR and CO_2 absorbing rate; when used with soda lime,

the OGR of each ORP (390 g) rose to 0.5 L/min, meeting O_2 demand of one person. The following attentions shall be paid to in use of potassium superoxide ORP: firstly necessary measures shall be taken to control alkaline dust and massive heat in condition of long time use; secondly the products from ORP reaction have to avoid contact with water in order to prevent generation of KOH which is strongly caustic.

In general, chemical oxygen, with high oxygen density and good independence, can be effectively used as emergency oxygen source for deployment in underground emergency refuge space, especially for high temperature and deep non-coal mines. In this way, additional heat from long-time use of chemical oxygen can be avoided. Meanwhile the safety and reliability of the oxygen supply system can be further increased, and the duration of life-support capabilities in emergency refuge facilities are improved.

A probe into the working procedures of crisis public relations in mine disasters

Xiaoming Shao, Huafeng Xu & Jingru Tang
North China Institute of Science and Technology, Beijing, P.R. China

ABSTRACT: By adopting document survey, questionnaire investigation and sampling survey, etc, this paper analyses and studies enterprises' crisis public relations in mine disasters, and puts forward the designs for both the related organizations and models of working procedures, thus offering some reference proposals and bringing some practical application value.

1 INTRODUCTION

In recent years China has launched a series of policies and measures to reinforce the supervision and management of coal industry. But according to the latest statistics from State Administration of Coal Mine Safety of China, in 2010 there were 970 disasters in small coal mines with 1, 700 deaths around the country, and in 2011, there were 1, 201 coal mine disasters with 1973 deaths throughout the country. This indicates that the current situation of coal mine safety production remains severe. Because coal mining belongs to underground operation, its process of production is complicated and dangerous. Thus, serious crisis like coal mine disasters often arise in the production. Correspondingly, the ability of crisis PR (abbreviated for Public Relations hereafter) of mining enterprises has encountered an acid test. However, the awareness of crisis PR of mining enterprises in China remains backward and the PR ability and level reflected in some emergencies like mine disasters is also quite undesirable. By far, in terms of the approaches adopted by some enterprises in the face of coal disasters, the author of this paper has conducted a survey, which reveals the outsiders' degree of satisfaction as Fig. 1.

A considerate number of collected documents have also revealed the similar results, which clearly warn that in China the crisis PR ability of the mining enterprises in the face of mine disasters need to be further improved.

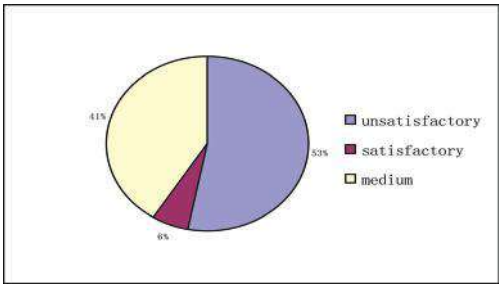

Figure 1. Questionnaire on the outsiders' degree of satisfaction.

2 CRISIS AND CRISIS PR

What is crisis? In the general sense, crisis refers to some emergent or disastrous accidents or events which endanger the welfare, the image or the survival of social organizations. And crisis is principally characterized by its urgency in time, severity of threat and the uncertainty of its further development.

Among the theorists, crisis PR can be divided into two types (LU 2002). In the narrow sense, crisis PR mainly refers to what has to be done to retrieve social understanding and good reputation through a series of PR campaigns when an enterprise is encountered with trust crisis, image crisis or work faults. But in the broad sense, crisis PR refers to the prevention, control and processing of crisis from the perspective of PR, which renders the crisis PR more thorough and integrated (LIU 2006).

3 CHARACTERISTICS OF MINE DISASTER CRISIS

3.1 *Burstiness*

Whether it is natural factors or human factors, one of the characteristics of mine disaster is its burstiness.

3.2 *Destructiveness*

Mine disaster is extremely destructive. It can lead to irreversible damage not only to the life and property of thousands of miners, but also to coal industry and the environment in China.

3.3 *Urgency*

On account of the unexpected burstiness and the severe destructiveness of mine disasters, rescue and relief work is very urgent and pressing. The action of crisis response and handling is quite time-conscious.

3.4 *Concern from media*

Mine disaster crisis often become the focus of social and media concern and the hot topics, thus becoming the content of news report and triggering different social response of the mine disaster (WANG 2009).

4 THE WORKING PROCEDURES OF MINE DISASTER CRISIS PR

4.1 *Design of organizational system*

A coal mining enterprise is expected to establish and improve crisis management institute. One is to establish a standing crisis management institute and make full preparation beforehand; the other is to establish an on-the-spot emergency team.

(1) Design of the framework of crisis management organization

A. Three-hierarchy organization and management model.

In terms of the form of the framework of crisis management organization in the mining enterprise, for any individual enterprise, it doesn't matter which one is the best option, but the top priority lies in the exploration of the most suitable one. In the general sense, the design of the framework of crisis management organization can adopt three-hierarchy organization and management model (See Fig. 2 below).

The first hierarchy is Crisis Management Committee, a decision-making organ made up of senior-/medium-level leaders, is a part-time matrix organization whose principal responsibilities include the formulation of crisis management policies, the making of Crisis Management Manual, the allocation of staff in Crisis Management Office, the inspection and supervision of the regular crisis management work, presiding over the regular crisis management meeting and being responsible for the resolution of some major crisis events, etc.
